Executive Summary

Energy Sector Planning and Analysis (ESPA) Services, under contract to the Department Of Energy's (DOE) National Energy Technology Laboratory (NETL), has estimated the performance and costs following three development pathways for natural gas fuel cell (NGFC) plant configurations with carbon capture and sequestration (CCS). The fuel cell technology applied is the planar, solid oxide fuel cell (SOFC) having split anode and cathode off-gas streams.

This report presents the results of a Pathway Study for natural gas fueled, fuel cell (NGFC) power systems with carbon capture and sequestration (CCS). The results quantify the performance and cost benefits for a series of projected gains made through the development of advances in the component technologies or improvements in plant operation and maintenance. The design and cost bases for this pathway study closely follows the bases applied in the NETL, 2010, Bituminous Baseline report so that direct performance and cost comparisons can be made with the conventional fossil-fuel power plant results estimated in that report [1].

Performance and cost projections for a baseline integrated gasification combined cycle (IGCC) power plant, a baseline natural gas combined cycle (NGCC) power plant, and prior coal-based integrated gasification fuel cell (IGFC) pathways, are compared with the results for the NGFC pathways. The results represent the potential future benefits of NGFC technology development. They also provide DOE with a basis to select the most appropriate development path for NGFC, and to measure and prioritize the contribution of its R&D program to future power systems technology.

This report covers the plant pathway scenarios characterized in Exhibit ES-1. Pathway 1 represents the NGFC plant with atmospheric-pressure SOFC and using a low-pressure, external auto-thermal reformer (ATR). Case 1-1 represents the baseline case for atmospheric-pressure SOFC technology, and applies SOFC operating, performance, and cost specifications representative of the current status of the developing SOFC technology. The high cold gas efficiency of the ATR, about 90 percent and the high methane content of its product syngas, about 30 mole-percent under dry conditions, promote attractive plant performance and cost.

A criterion for a maximum of 50 mole-percent water vapor in the anode gas has been hypothesized based on SOFC materials corrosion concerns [2]. This uncertain limitation translates to a maximum fuel utilization of 75 percent in Case 1-1. This baseline case is subject to both performance and cost variations in subsequent Cases 1-2 through 1-8, representative of a pathway development scenario progressing through cumulative advances in the cell degradation, the cell overpotential, cell cost, cell materials (water tolerance), inverter efficiency, and plant availability.

Pathway 2 applies a high-pressure auto-thermal reformer, and considers a configuration for an NGFC plant using pressurized SOFC. Pressurized SOFC can be configured in two general, alternative arrangements:

1. The anode off-gas oxy-combustor is followed by hot gas expander power generation (expansion ratio about 18). This requires an advanced expander needing CO₂ or steam cooling of hot parts. A heat recovery steam generator (HRSG) produces steam for power

generation, and the remaining, low-pressure, wet CO₂ stream is dehydrated and compressed (compression ratio about 149).

- The anode off-gas oxy-combustor is followed directly by a HRSG for steam bottoming power generation. The remaining, high-pressure, wet CO₂ stream is dehydrated and compressed (compression ratio about 8.4).

Configuration 2 is expected to be the least complex and most effective approach and is utilized for this evaluation. Baseline Case 2-1 is also followed by modifications representing performance and cost pathway development steps in Cases 2-2 through 2-4.

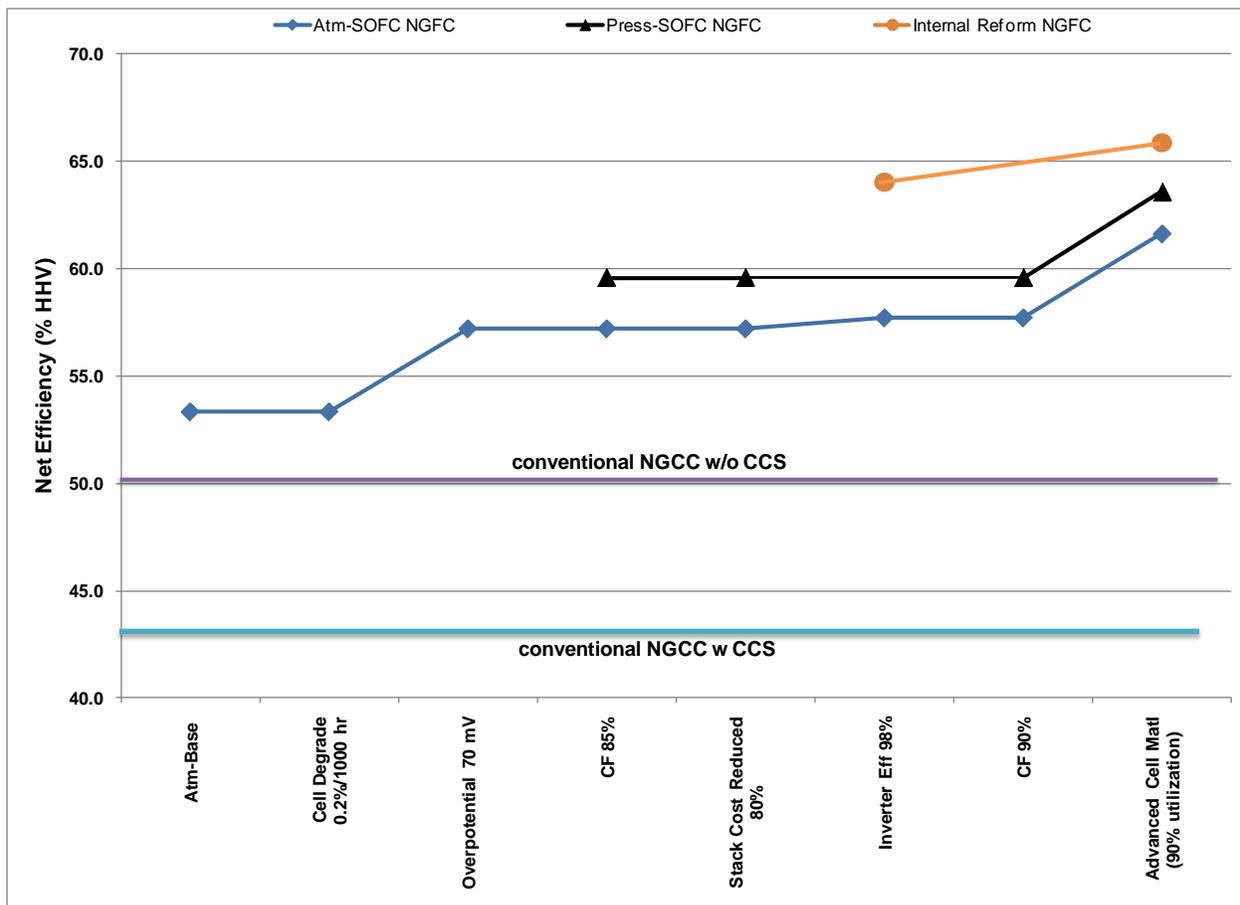

Exhibit ES-1 Pathway Study Matrix

| Case | Pathway Parameter | Fuel Utilization (%) | SOFC Pressure/ Overpotential | Capacity Factor (%) | Degradation (%/1000 hr) | Stack Cost (\$/kW SOFC) | Inverter Eff (%) |
|--|----------------------------------|----------------------|---------------------------------|---------------------|-------------------------|-------------------------|------------------|
| PATHWAY 1: ATMOSPHERIC-PRESSURE SOFC WITH EXTERNAL NG REFORMING | | | | | | | |
| 1-1 | Base Case | 75 | Atm/140 mV | 80 | 1.5 | 296 | 97 |
| 1-2 | Reduced Degradation | 75 | Atm/140 mV | 80 | 0.2 | 296 | 97 |
| 1-3 | Cell Performance | 75 | Atm/ 70 mV | 80 | 0.2 | 296 | 97 |
| 1-4 | Capacity Factor | 75 | Atm/70 mV | 85 | 0.2 | 296 | 97 |
| 1-5 | SOFC Cost Reduction | 75 | Atm/70 mV | 85 | 0.2 | 268 | 97 |
| 1-6 | Inverter Efficiency | 75 | Atm/70 mV | 85 | 0.2 | 268 | 98 |
| 1-7 | Capacity Factor | 75 | Atm/70 mV | 90 | 0.2 | 268 | 98 |
| 1-8 | Cell Materials (water tolerance) | 90 | Atm/70 mV | 90 | 0.2 | 268 | 98 |
| PATHWAY 2: PRESSURIZED-SOFC WITH EXTERNAL NG REFORMING | | | | | | | |
| 2-1 | SOFC Pressure | 75 | 285 psia/70 mV | 85 | 0.2 | 442 | 98 |
| 2-2 | Capacity Factor | 75 | 285 psia/70 mV | 90 | 0.2 | 442 | 98 |
| 2-3 | SOFC Cost Reduction | 75 | 285 psia/70 mV | 90 | 0.2 | 414 | 98 |
| 2-4 | Cell Materials (water tolerance) | 90 | 285 psia/70 mV | 90 | 0.2 | 414 | 98 |
| PATHWAY 3: ATMOSPHERIC-PRESSURE SOFC WITH INTERNAL REFORMING | | | | | | | |
| 3-1 | Internal Reforming | 83 | Atm/70 mV | 85 | 0.2 | Parameter | 98 |
| 3-2 | Cell Materials (water tolerance) | 90 | Atm/70 mV | 85 | 0.2 | Parameter | 98 |

In Pathway 3, the plant arrangement uses natural gas reforming internal to a hypothetical, as-yet undeveloped, atmospheric-pressure fuel cell having inserted reforming catalyst surfaces. Internal SOFC reforming catalysts are assumed to function successfully in this hypothetical arrangement, and the evaluation estimates the maximum acceptable cost of this advanced SOFC cell unit with these internal reforming surfaces added. The internal reforming of natural gas provides an additional source of cell cooling that promotes further increased plant efficiency.

Exhibit ES-2 compares the plant net efficiency for the NGFC pathway cases with conventional NGCC with and without CCS. Pressurization increases the plant net efficiency significantly. The NGFC pathway cases climb to efficiency greater than 65 percent for the pathway 3 scenario having advanced SOFC with internal reforming. All of the NGFC cases have efficiencies significantly above the conventional NGCC plant with or without CCS.

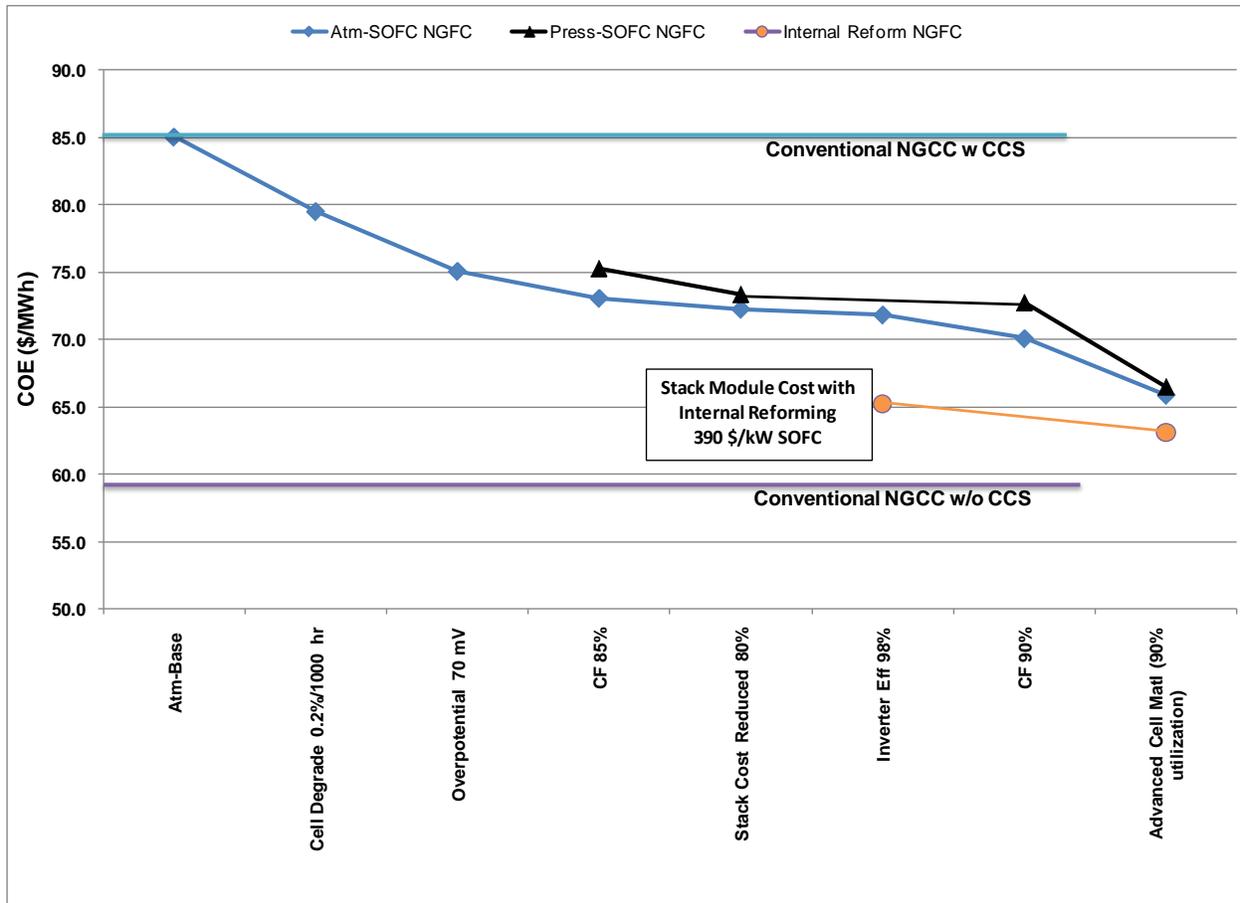

Exhibit ES-2 Pathway Efficiency Results

A similar pathway plot is shown in Exhibit ES-3 for the first-year COE. The price of natural gas is assumed to be 6.55 \$/MMBtu in the plot. Here, the pathway scenario 3 COE is included, even though the cost of the fuel cell stack with internal reforming has not been projected on an engineering basis, using a moderate stack cost of 390 \$/kW SOFC output, representing an

increase to the stack cost of 94 \$/kW for the internal catalyst structures. The COE for the NGFC pathway progresses to a level within about 4 \$/MWh of the COE for conventional NGCC without CCS, and about 22 \$/MWh below the COE for NGCC with CCS. The COE for pressurized-SOFC is higher than that of the atmospheric-pressure SOFC NGFC pathway cases due to the great increase in the stack enclosure cost with pressurization.

Exhibit ES-3 Pathway First-Years COE Results

Comparison between the performance and cost of NGFC pathway cases and the conventional NGCC with CCS is made in tabulated form in Exhibit ES-4. The NGFC pathway cases consume less than half as much water as the NGCC plants and have almost zero CO₂ emission. Note that in the pressurized-SOFC cases the CO₂ emission is estimated to be higher due to water condensation from the wet CO₂ product stream when it is at elevated pressure. The Total Overnight Costs of the NGFC pathway cases are comparable to, or lower than, those of the NGCC plant.

The baseline Case 1-1 NGFC plant has COE comparable to the conventional NGCC plant, but the pathway advances drop the COE almost 22 \$/kWh. Note that the Case 1-1 NGFC plant has a capacity factor of 80 percent versus 85 percent for the conventional NGCC plant. The avoided CO₂ cost for the baseline NGFC plant is comparable to the NGCC plant, but this drops

significantly for the advanced pathway cases. Cost results are not presented for the Case 3 plants along the NGFC pathway because no cost information is available for the fuel cell model cost with the internal reforming configuration. Exhibit ES-4, though, applies an assumed fuel cell cost for the internal reforming configuration that represents a 46% increase in the fuel cost, and shows the potential for significant advantage for this NGFC configuration over NGCC.

Exhibit ES-4 Performance and Cost Comparison with NGCC

| | NGCC ¹ with CCS | NGFC Case 1-1 | NGFC Case 1-8 | NGFC Case 2-1 | NGFC Case 2-4 | NGFC Case 3-1 ² | NGFC Case 3-2 ² |
|--|-------------------------------|------------------|------------------|------------------|------------------|-------------------------------|-------------------------------|
| Efficiency (% HHV) | 42.8 | 53.3 | 61.6 | 59.6 | 63.6 | 64.0 | 65.9 |
| Water Consumed (gpm/MW) | 6.3 | 2.9 | 1.6 | 2.2 | 1.2 | 1.7 | 1.3 |
| CO ₂ Emitted (kg/MWh) | 42.6 | 0.3 | 0.3 | 5.0 | 4.7 | 0.3 | 0.3 |
| TOC (\$/kW) | 1,497 | 1,482 | 1,169 | 1,490 | 1,529 | 1,231 | 1,174 |
| COE (\$/kWh) @ NG price 6.55 \$/MMBtu | 85.9 | 85.0 | 65.9 | 75.2 | 66.5 | 65.2 | 63.1 |
| Avoided CO ₂ Cost (\$/ton) | 32 | 29.6 | 7.9 | 18.6 | 8.7 | 7.2 | 4.8 |

1 – Uses a 7FB gas turbine and achieves 90% carbon capture

2 – Assumed stack cost with internal catalyst 390 \$/kW SOFC output

Exhibit ES-5 plots the first-year COE for the atmospheric-pressure SOFC pathway 1 and pathway 3 technologies as a function of the CO₂ emissions price. Also plotted are results for conventional fossil-fuel power plant technologies (supercritical PC without CCS, and NGCC with and without CCS) from the Bituminous Baseline report [1], and results for coal-based IGFC projection reported in the IGFC plant pathway study [3]. Included is an IGFC plant that incorporates the injection of natural gas into the coal syngas, with improved plant performance and cost resulting. The natural gas price is set at 6.55 \$/MMBtu in the exhibit, the price basis applied in the Bituminous Baseline report [1].

The curves for the NGFC cases and the IGFC cases are nearly horizontal lines due to their very small CO₂ emissions. The coal-based IGFC plant pathways are comparable or lower in COE than the NGFC pathway because of the much lower price of coal than natural gas (1.65 \$/MMBtu versus 6.55 \$/MMBtu). All of the fuel cell cases show advantage over the NGCC with CCS, except for the Case 1-1, baseline conventional coal gasifier IGFC case. Greatest cost advantage is shown for the advanced NGFC Case 1-8, the advanced NGFC case with internal reforming, and the advanced IGFC Case 3-7 with catalytic gasifier. No pressurized-SOFC cases are included due to their generally higher COE results.

The sensitivity of the plant cost-of-electricity (COE) to variable natural gas price is also identified for all of the cases in each pathway in Exhibit ES-6 for natural gas price of 4.0 \$/MMBtu, and Exhibit ES-7 for natural gas price of 12.0 \$/MMBtu. Lower natural gas price improves the COE of NGFC relative to the COE of coal-based IGFC. Increased natural gas price improves the COE of NGFC relative to the COE of NGCC due to the much higher efficiency of the NGFC plant.

Exhibit ES-5 First-Year COE Comparison with Other Fossil-Fuel Power Generation Technologies for Base Natural Gas Price of 6.55 \$/MMBtu

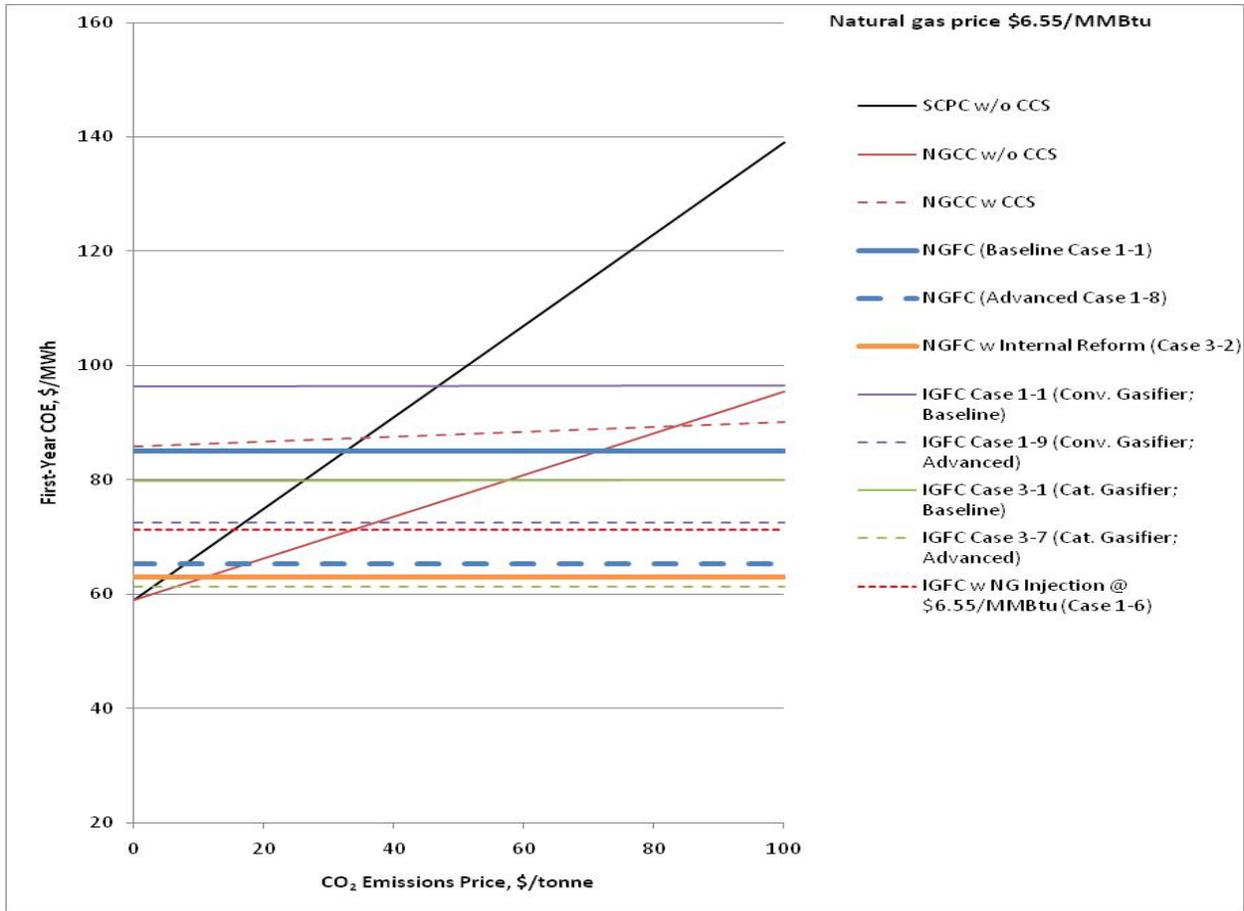

Exhibit ES-6 First-Year COE Comparison with Other Fossil-Fuel Power Generation Technologies for Base Natural Gas Price of 4.0 \$/MMBtu

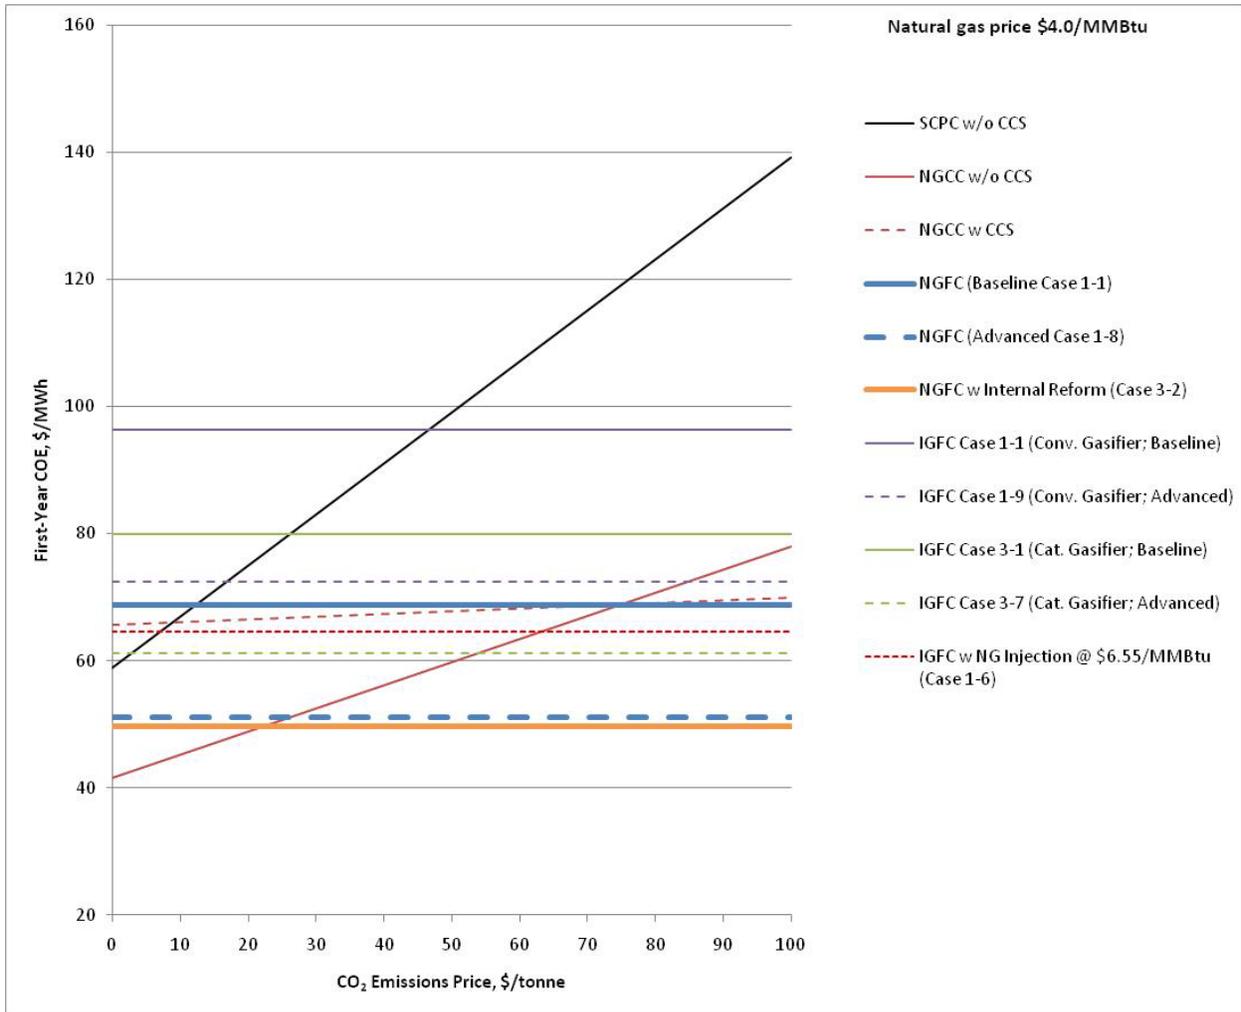

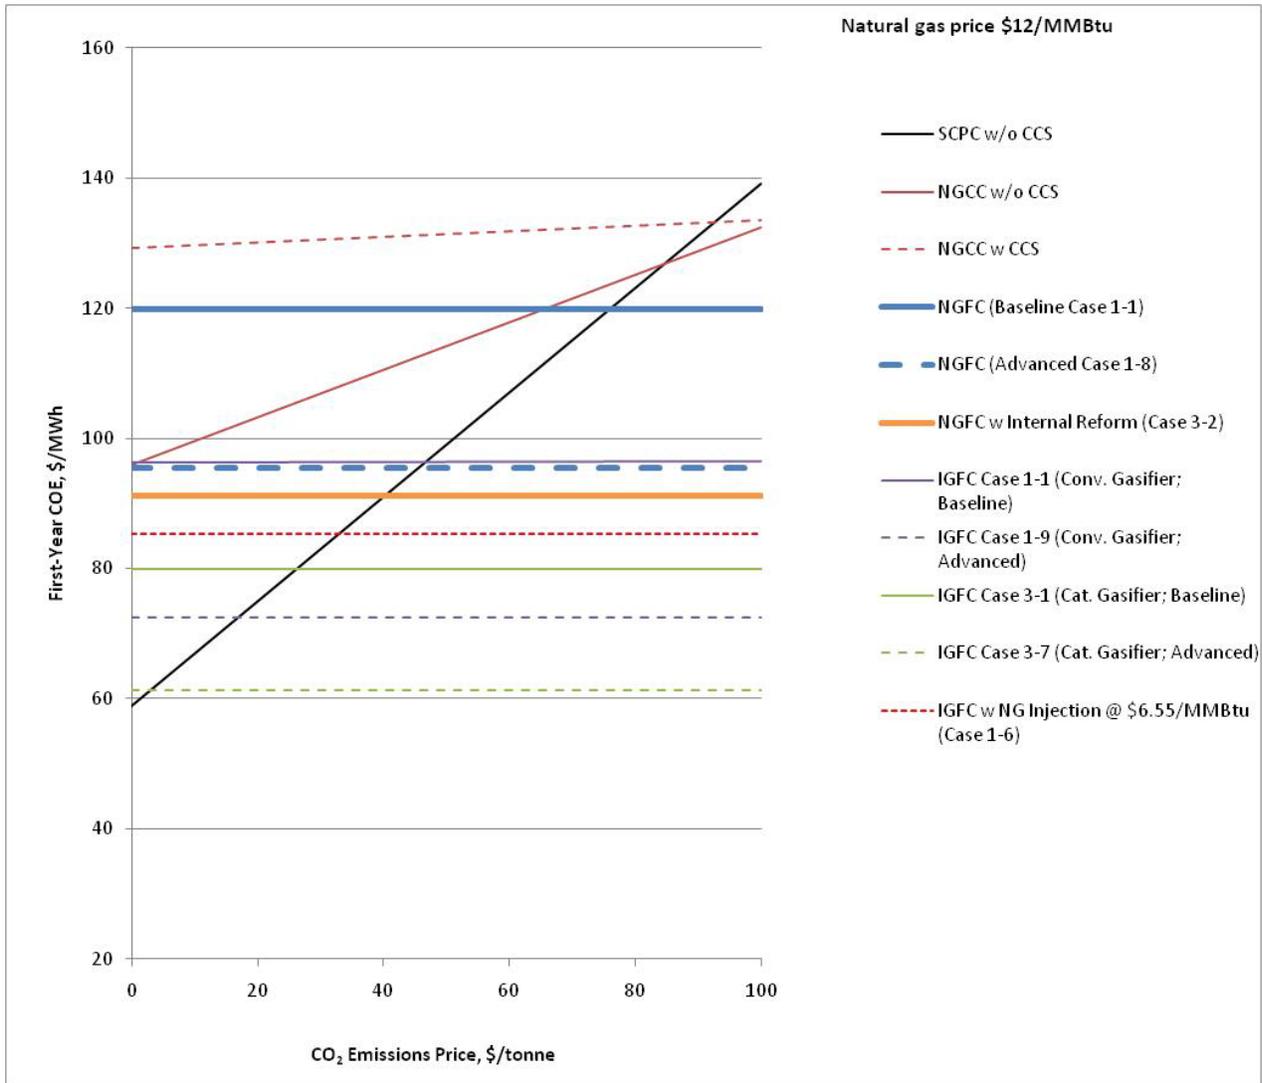

Exhibit ES-7 First-Year COE Comparison with Other Fossil-Fuel Power Generation Technologies for Base Natural Gas Price of 12.0 \$/MMBtu

General conclusions that can be drawn are:

- Pressurized SOFC for NGFC does not provide any COE advantage over atmospheric-pressure SOFC, although it provides a small efficiency advantage if the SOFC can tolerate high water vapor content (61 percent).
- The COE for NGFC is dominated by the cost of natural gas, with capital charges still being important.
- The COE for NGFC is attractive compared to conventional NGCC, but advances in NGCC technologies will narrow this advantage.
- The conventional coal gasifier-based IGFC plant has COE comparable to the NGFC plant, and the catalytic coal gasifier-based IGFC plant has a significant COE advantage over the NGFC plant for natural gas prices greater than about 6 \$/MMBtu.
- The NGFC plant with internal reforming has the potential for very high plant efficiency and COE in the low to mid 60 \$/kWh, comparable to the catalytic IGFC plant COE.
- Lower natural gas price will improve the COE of NGFC relative to the COE of coal-based IGFC and reduce the advantage of NGFC over NGCC.
- Increased natural gas price will improve the COE of NGFC relative to the COE of NGCC due to the much higher efficiency of the NGFC plant, although the higher natural gas price will favor the coal-based IGFC plant.
- Conventional coal gasifier-based IGFC with natural gas injection is an attractive option for low cost power generation with CCS.

1 Introduction

Energy Sector Planning and Analysis (ESPA) Services, under contract to the Department Of Energy's (DOE) National Energy Technology Laboratory (NETL), has estimated the performance and costs following three development pathways for natural gas fuel cell (NGFC) plant configurations with carbon capture and sequestration (CCS). The fuel cell technology applied is the planar, solid oxide fuel cell (SOFC) having split anode and cathode off-gas streams.

This report presents the results of a Pathway Study for natural gas fueled, fuel cell (NGFC) power systems with carbon capture and sequestration (CCS). The results quantify the performance and cost benefits for a series of projected gains made through the development of advances in the component technologies or improvements in plant operation and maintenance. The design and cost bases for this pathway study closely follows the bases applied in the NETL, 2010, Bituminous Baseline report so that direct performance and cost comparisons can be made with the conventional fossil-fuel power plant results estimated in that report [1].

Performance and cost projections for a baseline integrated gasification combined cycle (IGCC) power plant, a baseline natural gas combined cycle (NGCC) power plant, and prior coal-based integrated gasification fuel cell (IGFC) pathways, are compared with the results for the NGFC pathways. The results represent the potential future benefits of NGFC technology development. They also provide DOE with a basis to select the most appropriate development path for NGFC, and to measure and prioritize the contribution of its R&D program to future power systems technology.

This report covers the plant pathway scenarios characterized in Exhibit 1-1. Pathway 1 represents the NGFC plant with atmospheric-pressure SOFC and using a low-pressure, external auto-thermal reformer (ATR). Case 1-1 represents the baseline case for atmospheric-pressure SOFC technology, and applies SOFC operating, performance, and cost specifications representative of the current status of the developing SOFC technology. The high cold gas efficiency of the ATR, about 90 percent, and the high methane content of its product syngas, about 30 mole-percent under dry conditions, promote attractive plant performance and cost.

A criterion for a maximum of 50 mole-percent water vapor in the anode gas has been set based on SOFC materials corrosion concerns (2). This limitation translates to a maximum fuel utilization of 75 percent in Case 1-1. This baseline case is subject to both performance and cost variations in subsequent Cases 1-2 through 1-9, representative of a pathway development scenario progressing through cumulative advances in the cell degradation, the cell overpotential, cell cost, cell materials, inverter efficiency, and plant availability.

Pathway 2 applies a high-pressure auto-thermal reformer, and considers a configuration for an NGFC plant using pressurized SOFC. Pressurized SOFC can be configured in two general, alternative arrangements:

1. The anode off-gas oxy-combustor is followed by hot gas expander power generation (expansion ratio about 18). This requires an advanced expander needing CO₂ or steam cooling of hot parts. A heat recovery steam generator (HRSG) produces steam for power generation, and the remaining, low-pressure, wet CO₂ stream is dehydrated and compressed (compression ratio about 149).

2. The anode off-gas oxy-combustor is followed directly by a HRSG for steam bottoming power generation. The remaining, high-pressure, wet CO₂ stream is dehydrated and compressed (compression ratio about 8.4).

Configuration 2 is expected to be the least complex and most effective approach and is utilized for this evaluation. Baseline Case 2-1 is also followed by modifications representing performance and cost pathway development steps in Cases 2-2 through 2-4.

Exhibit 1-1 Study Matrix

| Case | Pathway Parameter | Fuel Utilization (%) | SOFC Pressure/ Overpotential | Capacity Factor (%) | Degradation (%/1000 hr) | Stack Cost (\$/kW SOFC) | Inverter Eff (%) |
|--|----------------------------------|----------------------|------------------------------|---------------------|-------------------------|-------------------------|------------------|
| PATHWAY 1: ATMOSPHERIC-PRESSURE SOFC WITH EXTERNAL NG REFORMING | | | | | | | |
| 1-1 | Base Case | 75 | Atm/140 mV | 80 | 1.5 | 296 | 97 |
| 1-2 | Reduced Degradation | 75 | Atm/140 mV | 80 | 0.2 | 296 | 97 |
| 1-3 | Cell Performance | 75 | Atm/ 70 mV | 80 | 0.2 | 296 | 97 |
| 1-4 | Capacity Factor | 75 | Atm/70 mV | 85 | 0.2 | 296 | 97 |
| 1-5 | SOFC Cost Reduction | 75 | Atm/70 mV | 85 | 0.2 | 268 | 97 |
| 1-6 | Inverter Efficiency | 75 | Atm/70 mV | 85 | 0.2 | 268 | 98 |
| 1-7 | Capacity Factor | 75 | Atm/70 mV | 90 | 0.2 | 268 | 98 |
| 1-8 | Cell Materials (water tolerance) | 90 | Atm/70 mV | 90 | 0.2 | 268 | 98 |
| PATHWAY 2: PRESSURIZED-SOFC WITH EXTERNAL NG REFORMING | | | | | | | |
| 2-1 | SOFC Pressure | 75 | 285 psia/70 mV | 85 | 0.2 | 442 | 98 |
| 2-2 | Capacity Factor | 75 | 285 psia/70 mV | 90 | 0.2 | 442 | 98 |
| 2-3 | SOFC Cost Reduction | 75 | 285 psia/70 mV | 90 | 0.2 | 414 | 98 |
| 2-4 | Cell Materials (water tolerance) | 90 | 285 psia/70 mV | 90 | 0.2 | 414 | 98 |
| PATHWAY 3: ATMOSPHERIC-PRESSURE SOFC WITH INTERNAL REFORMING | | | | | | | |
| 3-1 | Internal Reforming | 83 | Atm/70 mV | 85 | 0.2 | Parameter | 98 |
| 3-2 | Cell Materials (water tolerance) | 90 | Atm/70 mV | 85 | 0.2 | Parameter | 98 |

In Pathway 3, the plant arrangement uses natural gas reforming internal to a hypothetical, as-yet undeveloped, atmospheric-pressure fuel cell having inserted reforming catalyst surfaces. Internal SOFC reforming catalysts are assumed to function successfully in this hypothetical arrangement, and the evaluation estimates the maximum acceptable cost of this advanced SOFC cell unit with these internal reforming surfaces added. The internal reforming of natural gas provides an additional source of cell cooling promotes further increased plant efficiency.

The sensitivity of the plant cost-of-electricity (COE) to variable natural gas price is also identified for all of the cases in each pathway.

The balance of this report is organized as follows:

- Section 2 provides the basis for the technical and cost evaluations.
- Section 3 described the major plant components that are applied throughout the case studies.
- Section 4 describes the Pathway 1 plant simulations and presents the results for the atmospheric-pressure SOFC, NGFC cases and their corresponding pathway parameters.
- Section 5 describes the Pathway 2 plant simulations and presents the results for the pressurized-SOFC, NGFC cases and their corresponding pathway parameters.
- Section 6 describes the Pathway 3 plant simulations and presents the results for the atmospheric-pressure SOFC, NGFC cases with internal reforming, and their corresponding pathway parameters.
- Section 7 provides the reference list.

2 Pathway Study Basis

This document characterizes multiple configurations of a natural gas fuel cell (NGFC) plant, all configurations incorporating carbon capture and sequestration, and estimates overall plant performance and cost. The solid oxide fuel cell (SOFC) simulations represent the expected operating conditions and performance capabilities of planar fuel cell technology, having split cathode and anode off-gas steams, and operating at both atmospheric-pressure and elevated-pressure conditions.

The design and cost bases for this evaluation have been largely extracted from the NETL 2010 Bituminous Baseline Report (1) so that these NGFC plant results will be able to be directly compared to the baseline results for integrated gasification combined cycle (IGCC), pulverized coal (PC), and natural gas combined cycle (NGCC) plants presented in the Bituminous Baseline Report.

For each of the plant configurations in this study, a ChemCad process simulator (commercial process simulator by ChemStations, Houston, TX) model was developed and used to generate material and energy balances, which in turn were used as the design basis for the major equipment items. The major equipment characterizations were used to generate capital and operating cost estimates for the NGFC plants. Performance and process limits were based upon published reports, information obtained from vendors and users of the technology, performance data from design/build utility projects, and/or best engineering judgment as described in the Bituminous Baseline Report (1).

Capital and operating costs for most of the conventional equipment items were scaled from estimates made in the Bituminous Baseline Report. A current-dollar, first-year cost of electricity (COE) was calculated for each of the cases and is reported as the revenue requirement figure-of-merit.

The balance of this section documents the design basis common to all of the study cases, as well as environmental targets and cost assumptions applied in the study.

2.1 Site Description

The plants in this study apply the site description assumptions used in the Bituminous Baseline Report (1). The plants are fueled by natural gas, and are assumed to be located at a generic Midwestern site (Exhibit 2-2) operating at International Standards Organization (ISO) ambient conditions (Exhibit 2-1).

Exhibit 2-1 Site Ambient Conditions

| | |
|---|---------------|
| Elevation, m (ft) | 0 |
| Barometric Pressure, MPa (psia) | 0.10 (14.696) |
| Design Ambient Temperature, Dry Bulb, °C (°F) | 15 (59) |
| Design Ambient Temperature, Wet Bulb, °C (°F) | 11 (51.5) |
| Design Ambient Relative Humidity, % | 60 |

2.3.1 Estimation of Fuel Cell Operating Voltage

The fuel cell operating voltage has a large impact on the total plant performance and cost. An experimental basis or detailed modeling basis for estimating the SOFC operating voltage has not yet been established. For the pathway study cases, the SOFC cell operating potential has been estimated based on the evaluation of representative stack test data, using the difference between the anode inlet Nernst potential and a calibration-based over-potential to determine the operating potential. Thus, the operating voltage, V , is estimated as

$$V = E - OP$$

where E is the stack anode-inlet Nernst potential as calculated from the anode and cathode gas compositions, and OP is the calibration-based overpotential value. The Nernst potential is a function of the anode gas molar ratio of hydrogen to water vapor, the cathode gas oxygen mole fraction, the temperature, and pressure [4]. This procedure provides operating voltages that are comparable to SOFC vendor test results.

2.3.2 SOFC Carbon Deposition Control

The SOFC stack inlet anode gas composition can induce the formation of solid carbon deposits, which can disrupt the normal performance of the stack [4]. A criterion is applied in all of the cases to ensure anode gas inlet conditions where carbon deposition should not occur. The criterion for carbon deposit-free behavior is

$$A_o / A_c > 2.0$$

where A_o is the inlet anode gas total atomic oxygen content (with the main oxygen-containing species being CO , CO_2 , and H_2O), and A_c is the inlet anode gas total atomic carbon content (with the main species being CH_4 , CO , and CO_2). Anode gas recirculation using hot gas blowers, or syngas jet pumps maintains the inlet anode gas composition in a safe range by recirculating sufficient water vapor to maintain this criteria.

2.3.3 Maximum Anode Gas Water Vapor Content

Water vapor in excess of 50 mole-percent in the anode gas has been noted in the literature to promote cell materials corrosion issues with the current classes of materials in use (2). The maximum amount of water vapor in the anode gas occurs at its outlet and is controlled by the overall fuel utilization in the SOFC unit. In most of the study cases the outlet anode gas water vapor content is maintained at less than 50 mole-percent by selecting appropriate overall fuel utilization. In some other cases it is assumed that cell materials will be developed in the future that will allow high water vapor content and the fuel utilization is set at a higher value.

2.3.4 Estimation of Steam Bottoming Cycle Performance

The anode off-gas stream is combusted with oxygen, providing a hot combustion gas that passes through a heat recovery steam generation system that produces high-pressure process steam, low-pressure process steam, and high-pressure steam for power generation in a steam bottoming cycle. The steam bottoming cycle is a subcritical steam cycle that varies greatly in its steam conditions and capacity in the study cases, providing a relatively small proportion of the total plant generation output. In some cases the heat recovery temperature available is relatively low and results in poor steam superheat conditions. Rather than perform detailed design for each of

these unique steam bottoming cycles, a correlation method was applied that relates the steam bottoming cycle efficiency to the flue gas temperature available for steam generation [5].

For steam cycles limited to subcritical conditions, the correlation for the bottoming cycle efficiency is

$$\text{Efficiency (\% of heat absorbed)} = -0.000048223 T^2 + 0.100981 T - 5.747913$$

where T is the heat recovery inlet gas temperature (°C). For inlet temperatures greater than 648 °C, the efficiency is limited to 39.45 percent of the heat absorbed.

2.4 Plant Characteristics

The basis for the selection of several key plant characteristics is discussed below.

2.4.1 Plant Capacity Factor

The capacity factor for the baseline NGFC plant is assumed to be 80 percent, identical to that of the Bituminous Baseline Report IGCC plants, with the plant operating at 100 percent capacity. Other pathway study cases consider the economic benefits of increased plant capacity factors that will be realized with improved plant availability through greater operating experience, optimized maintenance procedures, and advanced monitoring. This study assumes that the plant would be dispatched any time it is available and would be capable of generating maximum capacity when online. Therefore the capacity factor and plant availability are equal.

2.4.2 Plant Sparing Philosophy

No major equipment spares are utilized in the plant. The SOFC cell stack is designed with excess cell capacity that can be activated during operation to maintain the fuel cell output nearly constant in response to cell performance degradation.

2.4.3 Plant Generating Capacity

The plant net generating capacity for all of the study cases is 550 MWe. This capacity was selected so that the plants would be comparable to other fossil fuel plants assessed in the Bituminous Baseline Report.

2.4.4 Number of Parallel Process Trains

All of the plants consist of single train processing for the ASU, the natural gas reformer area, and the power island. The CO₂ dehydration and compression system consists of four parallel trains.

2.4.5 Natural Gas Reforming Technology

The natural gas feed stream to the plant, delivered at 500 psia, is first preheated and expanded to the reformer working pressure. A portion of the natural gas feed (40 percent) is reformed with steam and oxidant in an auto-thermal reformer (ATR) to generate a high-heating value syngas [6] [7]. This is considered the most effective method to convert natural gas into a high-heating value syngas. This syngas is mixed with the remainder of the natural gas to yield a syngas having a methane content of about 30 mole-percent. In Pathway 3 the natural gas is reformed internally in an advanced SOFC unit having integral catalyst surfaces.

2.4.6 Natural Gas Desulfurization Technology

The natural gas is desulfurized from its assumed 5 ppmv total sulfur content reduced to 100 ppbv total sulfur using the low-temperature, TDA Research Inc. SulfaTrap™ sorbent before it is introduced to the plant [8].

2.4.7 SOFC Power Island Technology

The SOFC power island generating components consist of a natural gas expander that expands the natural gas from its high-pressure condition down to the operating pressure of the reformer unit; a syngas expander that expands the syngas from its reformer outlet condition down to the operating pressure of the fuel cell unit; the SOFC fuel cell unit with DC-AC inverters; an anode off-gas oxy-combustor; a heat recovery steam generator that captures heat from the combusted anode off-gas; and a steam bottoming cycle.

The SOFC unit ancillary components consist of cathode air blowers, cathode heat exchangers that recuperatively heat the cathode air up to the fuel cell inlet temperature, cathode advanced hot gas recycle blowers, anode heat exchangers that recuperatively heat the anode gas up to the fuel cell inlet temperature, and anode gas advanced hot gas recycle blowers.

The heat recovery steam generator produces low-pressure and high-pressure process steam, and high-pressure power steam for the subcritical steam bottoming cycle. The cooling water system uses a mechanical draft, wet cooling tower arrangement.

In Pathway 2, in which pressurized SOFC operation is used, the cathode air is compressed to the pressurized fuel gas inlet pressure, and no cathode gas recycle is used. The cathode off-gas is expanded to atmospheric pressure to generate power to drive the cathode air compressor. Anode gas recycle is accomplished using a syngas-driven jet pump in this pressurized case.

2.4.8 SOFC CO₂ Capture Technology

The anode off-gas is combusted using 99.5 percent oxygen in an advanced oxy-combustor with excess oxygen limited to 1 mole percent. The combusted anode gas consists of CO₂, water vapor, excess oxygen, and minor traces of contaminants (sulfur species, and NO_x). This combustion gas is dehydrated and compressed to the sequestration pressure of 2,200 psig. In its dry state it will contain 2 to 3 mole percent oxygen. It is assumed that this is acceptable, although it far exceeds the currently adopted criteria for CO₂ sequestration gas.

2.5 Environmental Requirements

The emissions estimated to result from the NGFC plant are far lower than any current environmental regulations for fossil fuel power plants. It is assumed that plant permitting requirements will be based on these capabilities.

2.5.1 NGFC Emission Perspective

The NGFC plant emissions are very limited because the total sulfur content in the natural gas must be controlled to less than 100 ppbv to protect the fuel cell materials, the oxy-combustor is a low NO_x producing combustor, and all of the remaining contaminant species are sequestered with the CO₂. The plant has nearly 100 percent removal of all environmental contaminants, including CO₂. Water usage is also estimated to be extremely low in the NGFC plants. The

pipeline natural gas is assumed to contain no particulate matter or trace elements, resulting in no control requirements being needed other than natural gas desulfurization.

2.5.2 CO₂ Product Specification

Exhibit 2-4 gives the pipeline specification used for this study (1). This specification assumes carbon steel for the pipeline material. The potential to co-sequester other contaminants with CO₂ does not occur, and the oxy-combustor off-gas will contain only very small quantities of SO₂, NO_x, and CO.

Note that in this evaluation, the dried CO₂ sequestration stream will contain 2–3 mole percent oxygen. It is assumed that this will be acceptable for the CO₂ piping system and the geological storage formation.

Exhibit 2-4 CO₂ Pipeline Specification

| | |
|------------------------------------|-----------------------------|
| Compression Pressure (psia) | 2,200 |
| CO₂ | not limited |
| Water | dehydration (0.015 vol%) |
| N₂ | not limited |
| O₂ | <100 ppmv |
| Ar | not limited |
| NH₃ | not limited |
| CO | not limited |
| Hydrocarbons | <5 vol% |
| H₂S | <1.3 vol% |
| CH₄ | <0.8 vol% |
| H₂ | Uncertain |
| SO₂ | <3 vol% |
| NO_x | Uncertain |

2.6 Economic Analysis

Capital and production cost estimates follow the economic basis applied in the Bituminous Baseline Report. The Bituminous Baseline Report provides factored estimates developed for each plant section for conventional fossil fuel plants, and this study scales those costs for comparable plant sections that appear in the NGFC plants. Costs were factored using operating variables and scaling exponents appropriate for each system account. Costs for unique equipment in the NGFC plants were estimated using available generalized cost correlations, or using cost estimates for comparable equipment reported in other power plant studies. In the case of the SOFC stack components, the estimated capital cost were based on a current NETL technology development cost goal and SOFC vendor projections.

2.6.1 Plant Maturity

The pathway plants simulated include technologies at different commercial maturity levels, and the NGFC plants contain some advanced, immature technologies. The SOFC and oxy-combustion technologies are immature and unproven at commercial scale in power generation applications.

The developing SOFC technology performance and cost has been estimated through scaling to commercial levels by the SOFC developers. While commercial pre-combustion CO₂ removal technology could be applied in place of the oxy-combustion based CO₂ removal, the advantages of oxy-combustion approach over pre-combustion CO₂ removal are so large that the oxy-combustion technology merits development support.

The current-dollar, first-year COE was calculated for each case using economic parameters for high-risk technologies resulting in a capital charge factor of 0.1773. The capital component of the COE was calculated using the plant Total Overnight Cost (TOC).

2.6.2 Contingency

Both the project contingency and process contingency costs represent costs that are expected to be spent in the development and execution of the project that are not yet fully reflected in the design. It is industry practice to include project contingency in the Total Plant Cost (TPC) to cover project uncertainty and the cost of any additional equipment that would result during detailed design. Likewise, the estimates include process contingency to cover the cost of any additional equipment that would be required as a result of continued technology development.

The project and process contingencies applied were taken from the Bituminous Baseline Report for comparable equipment items. The contingencies applied are listed in Exhibit 2-5.

2.6.3 Operating Labor

Operating labor cost was determined based on of the number of operators required for each specific case. The average base labor rate used to determine annual cost is \$34.65/h. The associated labor burden is estimated at 30 percent of the base labor rate. Seven operators per shift are assumed in all cases except for Pathway 3, where there is no ATR system to operate and it is assumed that six operators are needed.

Exhibit 2-5 Project and Process Contingencies

| Equipment Component | Project Contingency | Process Contingency |
|--|---------------------|---------------------|
| Natural Gas Desulfurization | 0 | 0 |
| Auto-thermal Reformer & Accessories | | |
| ATR & Syngas Cooler | 0 | 15 |
| ASU & Oxidant Compressor | 0 | 10 |
| CO ₂ Drying & Compression | 0 | 20 |
| SOFC Power Island | | |
| NG expander/Syngas expander/Oxy-combustor expander | 15 | 15 |
| SOFC Reactor | 0 ¹ | 0 ¹ |
| Cathode Air Blower/Compressor | 15 | 15 |
| Cathode Recycle Gas Blower | 15 | 15 |
| Cathode Heat Exchanger | 15 | 15 |
| Anode Heat Exchanger | 15 | 15 |
| Anode Recycle Gas Blower/ Jet Pump | 15 | 15 |
| Oxy-Combustor | 0 | 0 |
| Feedwater & Misc. BOP Systems | 0 | 23 |
| HRSG, Ducting & Stack | 0 | 10 |
| Steam Power System | 0 | 14 |
| Cooling Water System | 0 | 20 |
| Accessory Electric Plant | 0 | 19 |
| Instrumentation & Control | 0 | 17 |
| Improvement to Site | 0 | 30 |
| Buildings & Structures | 0 | 16 |

1 – No contingency is applied because the SOFC reactor cost is based on an NETL development goal

2.6.4 First-Year, Current-Dollar Cost of Electricity

The figure of merit, the first-year cost-of-electricity (COE), will be determined as specified in the NETL Quality Guidelines for Energy System Studies using a simplified model derived from the NETL Power Systems Financial Model [9]. The cost premises applied in the Bituminous Baseline Report are applied here. The NGFC plants are treated as high-risk plants to generate COE values.

The first year cost of natural gas used in this study is \$6.21/MMkJ (\$6.55/MMBtu) (2015 cost of natural gas in 2007 dollars). This cost was determined in the Bituminous Baseline Report.

2.6.5 Capital Costs

Following the basis in the Bituminous Baseline Report, with costs in June 2007-dollars, the capital costs at the Total Overnight Cost (TOC) level include equipment, materials, labor, indirect construction costs, engineering, owner's costs, and contingencies. Where applicable, the cost of major plant sections in the study case plants were based on a scaled estimate from the Bituminous Baseline Report, applying the general cost-scaling equation

$$C = N * (C_{ref} / N_{ref}) * [(F / N) / (F_{ref} / N_{ref})]^S$$

Where Cost is the cost of the study case plant section,

N is the number of parallel sections in the study case plant,

C_{ref} is the cost of the reference plant section,

N_{ref} is the number of parallel sections in the reference plant,

F is the scaling capacity for the study case plant section,

F_{ref} is the scaling capacity for the reference plant section, and

S is the scaling factor characteristic of the plant section equipment (a fraction usually between 0.5 and 0.8).

In addition:

- The estimates represent nth-of-a-kind offerings for everything except the natural gas reforming system, the natural gas desulfurization system, the CO₂ compression system, and oxy-combustor system, which are considered initial commercial offerings (i.e., first of a kind).
- The estimates represent a complete power plant facility, with the exception of the exclusions listed below.
- The estimate boundary limit is defined as the total plant facility within the “fence line,” and includes the water supply system, and CO₂ transport storage and monitoring. Electrical output “within the fence line” terminates at the high voltage side of the main power transformers.
- Costs are grouped according to a process/system oriented code of accounts; all reasonably allocable components of a system or process are included in the specific system account in contrast to a facility, area, or commodity account structure.

CO₂ transportation, storage and monitoring (TS&M) costs are included in the study following the Bituminous Baseline Report estimation procedure.

2.6.6 SOFC Power Island Capital Cost

The rationale used to estimate the cost of the SOFC power island for both atmospheric-pressure SOFC and pressurized SOFC applications is described here. The cost basis for the key SOFC Unit (the cell Blocks arranged as Stack Modules, their Enclosures, and the DC-AC Inverters) is identified. The major basis for the estimates made here are a DOE 2010 SOFC cost goal, and cost estimates generated by Fuel Cell Energy Inc. (FCE) [10] [11] .

Exhibit 2-6 illustrates the NGFC power island configuration using FCE terminology. The NGFC power island consists of an array of factory assembled SOFC Sections, a syngas expander, an oxy-combustor, and steam bottoming components that are separately shipped and installed with the SOFC Sections at the plant site. Each SOFC Section consists of an array of Stack Modules, with the anode and cathode blowers and heat exchangers being factory assembled and shipped as complete, integrated units to the power plant. Each SOFC Unit contains, using FCE terminology:

- SOFC “Blocks” arranged as Stack Modules,

- an Enclosure for each Stack Module,
- a DC-AC Inverter for each Stack Module.

A basic “cell” has an area of 550 cm^2 , and a Block contains 96 cells, or $52,800 \text{ cm}^2$ of active cell area. Each Stack Module holds 64 Blocks, and each Section holds 42 Stack Modules.

The DOE 2010 SOFC cost goal for the factory-assembled, atmospheric-pressure SOFC Blocks and Enclosures is 175 \$ per kW of plant net power, in June 2007 dollars. This cost is interpreted as the factory-assembled cost, not including transportation to the site, and labor and materials for the site foundation, and for placing the equipment at the site. The other Section components (blowers and heat exchangers) are separately estimated as factory-installed items. The other power island components (syngas expander, oxy-combustor, and steam bottoming components) are estimated as separately shipped components installed at the plant site.

It is assumed that the atmospheric-pressure SOFC Unit will have a power density of 400 mW/cm^2 since the temperature, fuel utilization, and syngas composition will vary only over a limited range generally selected for high levels of performance. The SOFC Blocks and Enclosure cost must be converted to units of dollars per kW of SOFC power, rather than dollars per kW of net plant power, in order to be able to use the cost for general plant cost estimation. The ratio of the net plant power to the SOFC power ranges from approximately 0.94 to 1.0 for prior plant simulations performed, and a value of 0.945 from a base plant configuration is applied here to produce a cost for the integrated Blocks and Enclosures of 165 \$/SOFC kW, in June 2007 dollars.

From FCE estimates, the separate Enclosures cost is about 25 \$/SOFC kW, and thus the integrated Blocks cost about 140 \$/SOFC kW. With the power density being 400 mW/cm^2 , and assuming an Inverter efficiency of 97 percent, the integrated Blocks cost per cm^2 of active surface area is $140/1,000 * 400/1,000 * 0.97 = 0.054 \text{ \$/cm}^2$ active surface area. This value is used to estimate the pressurized SOFC Unit cost.

The Inverter cost is estimated from FCE information as 82 \$/SOFC kW using NIST SiC inverter technology. This advanced technology is considerably cheaper than the more conventional Satcon technology.

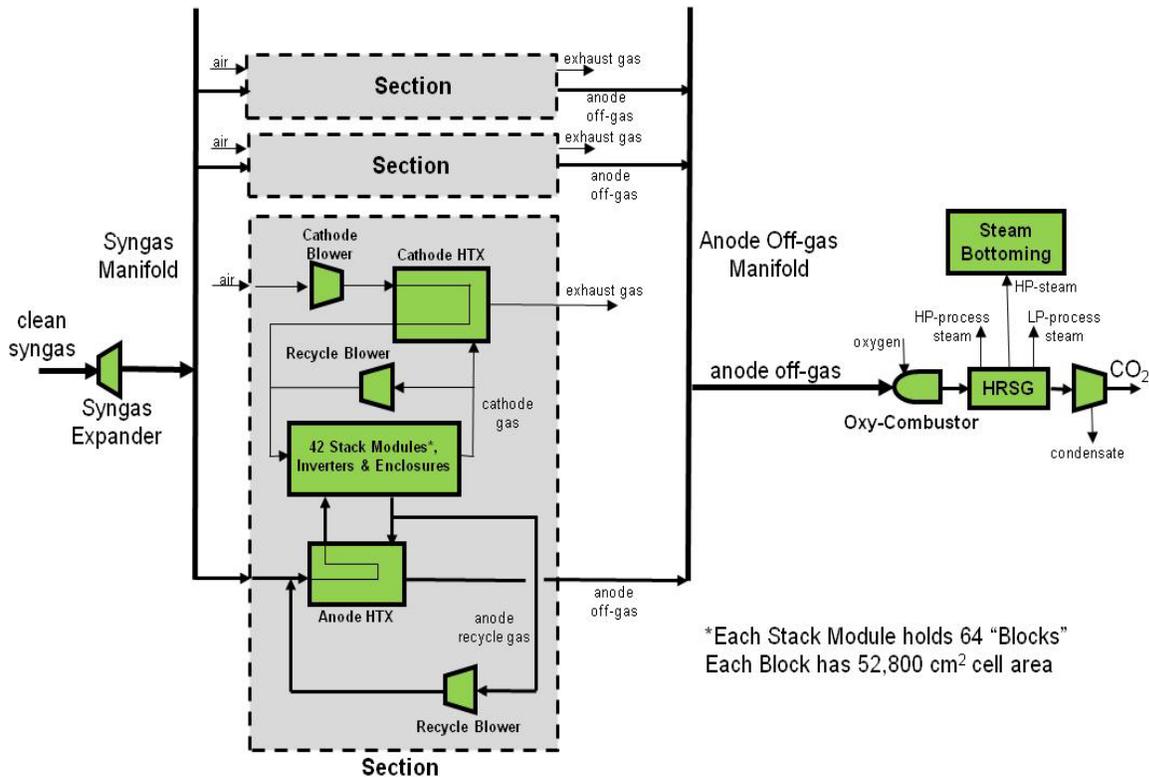

The total cost of the atmospheric-pressure, integrated SOFC Units (Blocks, Enclosures, Inverters) is $165 + 82 = 247 \text{ \$/SOFC kW}$. To this is also added the rough estimate for the cost of transport and placement of the Sections ($12 \text{ \$/SOFC kW}$) and the cost for the Section foundations at the site ($37 \text{ \$/SOFC kW}$), for a total installed cost of $296 \text{ \$/kW}$ of SOFC AC generation.

A similar configuration is assumed to apply for the pressurized SOFC Unit, where the Enclosures now require pressure capability to a 300 psia design pressure. It is assumed that the pressurized cells will have a fixed power density of 500 mW/cm^2 , increased from 400 mW/cm^2 by the enhanced performance resulting from pressurization.

The integrated Block cost will then be $0.054 / (500 * 0.97) * 1 \times 10^6 = 111 \text{ \$/SOFC kW}$, based on the atmospheric Blocks cost of $0.054 \text{ \$/cm}^2$. The Enclosure cost is estimated to be a factor of 10 higher than the atmospheric-pressure enclosure cost to house the Modules having dimensions of roughly 10-ft width by 15-ft length by 10-ft height. This makes the Enclosure cost $25 * 400/500 * 10 = 200 \text{ \$/SOFC kW}$.

With the Inverter cost being the same as in the atmospheric-pressure application, the total cost of the pressurized, integrated SOFC Unit (Blocks, Enclosures, Inverters) is $111 + 200 + 82 = 393$ \$/SOFC kW. With transportation, placement, and foundations, the total cost is 442 \$/kW of SOFC AC generation.

Exhibit 2-6 SOFC Power Island Configuration Showing Section Components

2.6.7 Production Costs and Expenses

The production, or operations and maintenance (O&M), costs described in this section pertain to charges associated with operating and maintaining the power plants. These are estimated directly from the procedures described in the Bituminous Baseline Report. Exhibit 2-7 lists the catalyst and chemicals initial fill and consumption rate, and price bases applied in the evaluation.

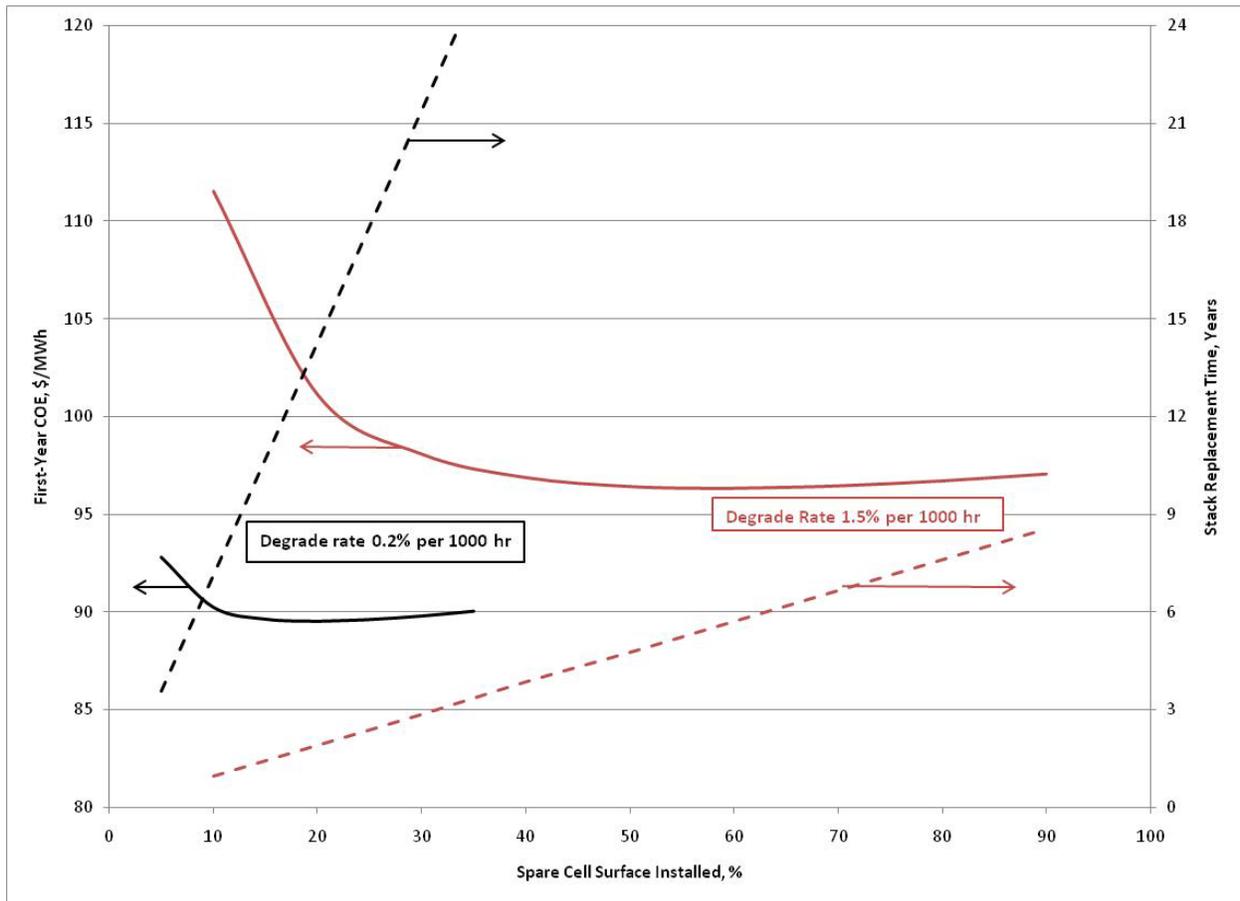

Exhibit 2-7 Catalyst and Chemicals Consumption and Cost Basis

| Chemical/Catalyst | Initial Fill Scaling Factor | Use Rate Scaling Factor | Price Assumption | Source |
|-----------------------|-----------------------------|-------------------------|-----------------------|----------------------|
| MU & WT chemicals | NA | Raw water consumption | 0.17 \$/lb | NETL (1) |
| ATR catalyst | Syngas rate | Syngas rate | 499 \$/m ³ | Engineering Estimate |
| TDA NG sulfur sorbent | Sulfur capture rate | Sulfur capture rate | 1.5 \$/lb | Vendor data |

Another significant production cost is associated with cell performance degradation. Test data indicate that the cell performance degrades at less than 1 percent per 1,000 hours and levels as low as 0.05 percent per 1,000 hours can be considered [12]. The SOFC cells will operate with constant cell voltage and with decreasing cell current, resulting in degraded plant power generation with time. Spare cell capacity in the form of Blocks and Enclosures must be incorporated into the SOFC system design to be “switched on” at regular periods (1,000-hour intervals assumed) to increase the operating cell surface. This will maintain a near-constant plant power output from the SOFC cells to avoid total power plant performance degradation.

It is assumed in this evaluation that spare SOFC cell surface (Blocks and Enclosures) will be provided at a cost of 165 \$/SOFC kW based on the cost considerations in Section 2.6.6, and with the spare surface based on the cell degradation rate and the selected cell replacement period. The entire cell surface would be replaced (the Blocks only) at a cost of 140 \$/SOFC kW, with an assumed 10 percent discount rate after the cell has degraded the selected extent.

Exhibit 2-8 shows an illustration of the impact of the cell degradation rate and the spare cell surface initially installed in the plant on the plant first-year cost of electricity (COE) for plants having cell degradation rates of 1.5 percent per 1000 hours and 0.2 percent per 1000 hours. If too little spare cell surface is installed the COE will be high due to the need to frequently replace the stacks. Increased spare cell surface installation leads to a relatively flat COE region where the COE is little influenced by the amount of spare surface installed and the stack replacement period can be selected for best plant maintenance schedule. An optimum spare surface installed exists and this is applied in the pathway study. For 1.5 percent per 1000 hour degradation, the optimum spare surface is 58.4 percent with 5.5 year stack replacement time. For 0.2 percent per 1000 hour degradation, the optimum spare surface is 17 to 20 percent with 11 to 13 year stack replacement time.

Exhibit 2-8 Impact of Cell Degradation and Cell Stack Replacement Period

2.6.8 Owner's Costs

The owner's costs to be included in the TOC estimate were estimated following the procedures described in the Bituminous Baseline Report.

2.7 Raw Water Consumption

A water balance was performed for each case on the major water consumers in the process. The total water demand for each subsystem was determined and internal recycle water available from various sources like boiler feedwater blowdown and condensate from CO₂ gas compression was applied to offset the water demand. The difference between demand and recycle is raw water withdrawal. Raw water withdrawal is the water removed from the ground or diverted from a surface-water source for use in the plant. Raw water consumption is also accounted for as the portion of the raw water withdrawn that is evaporated, transpired, incorporated into products or otherwise not returned to the water source it was withdrawn from.

Raw water makeup was assumed to be provided 50 percent by a publicly owned treatment works (POTW) and 50 percent from groundwater. Raw water withdrawal is defined as the water metered from a raw water source and used in the plant processes for any and all purposes, such

as cooling tower makeup, or boiler feedwater makeup. The difference between withdrawal and process water returned to the source is consumption. Consumption represents the net impact of the plant on the water source.

Boiler feedwater blowdown was assumed to be treated and recycled to the cooling tower. The cooling tower blowdown was assumed to be treated and 90 percent returned to the water source with the balance sent for evaporation.

The largest consumer of raw water in all cases is cooling tower makeup. It was assumed that all cases utilized a mechanical draft, evaporative cooling tower, and all process blowdown streams were assumed to be treated and recycled to the cooling tower. A cooling water temperature of 16°C (60°F) with an approach of 5°C (8.5°F) is used. The cooling water range was assumed to be 11°C (20°F). The cooling tower makeup rate was determined using the following [13]:

- Evaporative losses of 0.8 percent of the circulating water flow rate per 10°F of range
- Drift losses of 0.001 percent of the circulating water flow rate
- Blowdown losses were calculated as follows:
 - $\text{Blowdown Losses} = \text{Evaporative Losses} / (\text{Cycles of Concentration} - 1)$

where cycles of concentration is a measure of water quality, and a mid-range value of 4 was chosen for this study.

The water balances presented in subsequent sections include the water demand of the major water consumers within the process, the amount of process water returned to the source, and the raw water consumption, by difference.

3 NGFC Plant Major Process Areas

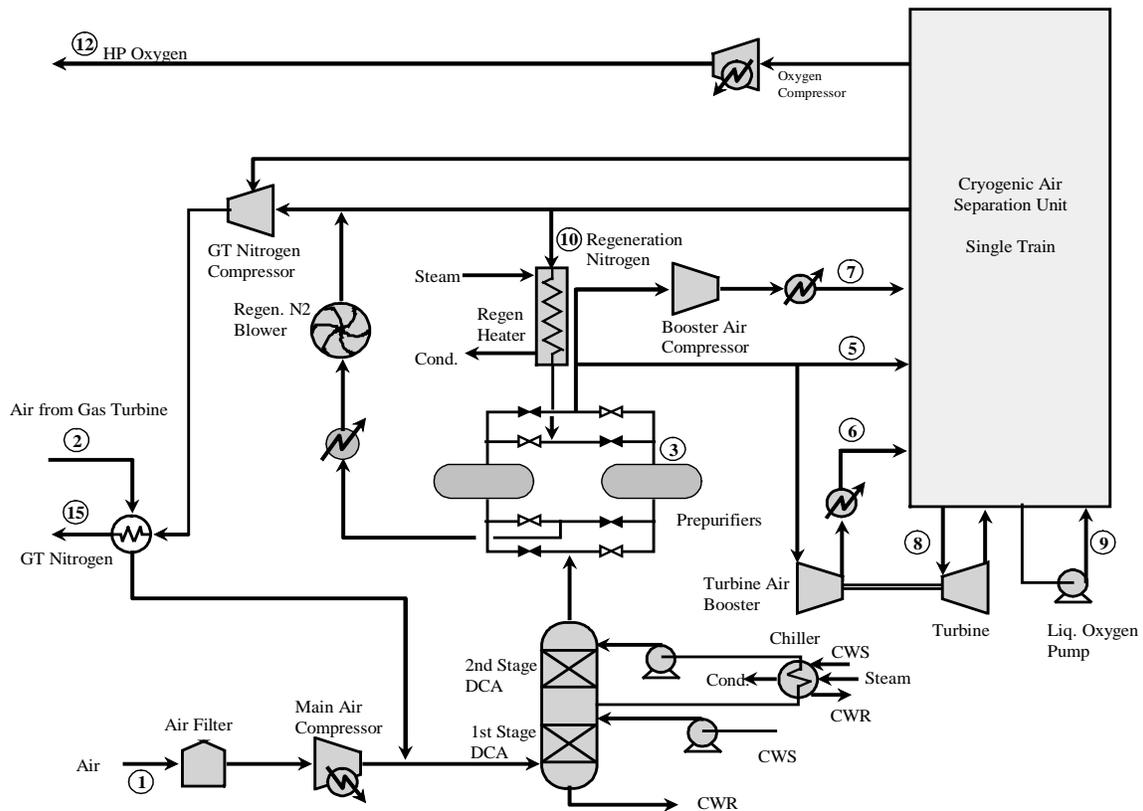

The NGFC plant consists of several integrated process areas, the primary ones being the air separation unit, the reformer area, the power island, and the CO₂ dehydration and compression area. Descriptions of these areas and their selected technologies are presented in this report section. Additional case-specific performance information is presented in the relevant pathway sections.

3.1 Air Separation Unit

The air separation unit (conventional cryogenic ASU) generates oxidant for use in two sections of the NGFC plant: the natural gas auto-thermal reformer, and the anode off-gas oxy-combustor. In this study, the ASU main air compressor discharge pressure was set at 0.5 MPa (79 psia), providing oxygen product at sufficient pressure, 0.16 MPa (23 psia), to operate the oxy-combustor for the atm-pressure SOFC applications. The ASU is designed to generate 99.5 percent pure oxygen for NGFC applications to maintain the sequestered CO₂ stream with low nitrogen and argon content. There is no opportunity for ASU air-side integration in the NGFC plant like there are in IGCC plants, and there is no need or benefit from syngas nitrogen dilution in the NGFC. In this study, the ASU nitrogen product is used only for inert gas needs, with the remainder vented.

The air separation plant is designed to produce 99.5 mole percent O₂ for use in the ATR and anode off-gas oxy-combustor. The plant is designed with a single production train. The air compressor providing air to the process is powered by an electric motor. Nitrogen is also recovered, and used as inert gas, with the major portion being vented. The ASU simulation applied for this evaluation is greatly simplified with component separators, and the ASU performance is extrapolated from reported plant performance data.

A process schematic of a typical cryogenic ASU is shown in Exhibit 3-1. The Bituminous Baseline report [1] provides a detailed description of the cryogenic ASU process configuration and functions.

Exhibit 3-1 Typical ASU Process Schematic

3.2 Natural Gas Reforming Area

Various types of natural gas reformers are commercially available to generate a syngas suitable for the NGFC power generation application. The major types include the steam-methane reformers, the partial oxidation reformer, and the auto-thermal reformer (ATR). Of these, the ATR is expected to be the cheapest and most reliable reformer available for the simple generation of a hydrogen, carbon monoxide syngas [6, 7] and is selected for use in this evaluation.

The ATR was first developed by Halder Topsoe in the late 1950s. It consists of a refractory-lined pressure vessel that contains two reaction zones, a combustion zone followed by a catalytic reforming zone. Steam is mixed with pressurized natural gas in proportions that prevent soot formation within the high-temperature combustion zone. This mixture is preheated and fed to a burner nozzle fired with a pressurized, preheated oxygen stream. The burner nozzle is directed into the ATR combustion zone where partial oxidation of the fuel, heating, and recirculation mixing occurs, with temperature reaching up to 1900°C. Soot is prevented from forming in this zone if sufficient steam is provided.

The partially oxidized mixture then flows uniformly through internal, refractory distribution devices, into the catalytic reaction zone where methane is reformed and the water gas shift reaction proceeds. A near equilibrium condition is reached in this Ni-based catalyst zone, with

exit temperature in the range of 900 to 1100°C. The Ni-based catalyst may be in the form of a packed bed or a honeycomb-supported structure that allows greater space velocity with acceptable pressure drop. Pressurized operation of the ATR for various synthesis applications is typical at pressures up to 60 atmospheres, but low-pressure operation is also feasible.

Exhibit 3-2 lists the operating conditions selected and the assumptions applied for the ATR in the study cases (Pathways 1 and 2) in this evaluation. In both pathways, 40 percent of the total plant natural gas is reformed. Pathway 1 uses an atmospheric-pressure SOFC application and the ATR is operated at low pressure. The ATR could have been operated at a high pressure, like that used in Pathway 2, with the SOFC fuel gas expanded to the SOFC inlet pressure.

It is assumed that there is no soot formation or carbon loss in the ATR, and equilibrium syngas composition is achieved. The reformer syngas product is mixed with the remaining, 60 percent of the natural gas feed, resulting in a high methane content in the SOFC fuel gas stream that is near the upper limit of what is expected to be currently operable in the SOFC unit.

Exhibit 3-2 Natural Gas Reformer Section Operating Conditions and Assumptions

| | Pathway 1 | Pathway 2 |
|---|---------------|---------------|
| Natural Gas Reformer | | |
| Technology | ATR | ATR |
| Number reformers in parallel | 1 | 1 |
| Exit temperature, °C (°F) | 927 (1700) | 982 (1800) |
| Exit pressure, MPa (psia) | 0.14 (20) | 3.10 (450) |
| NG reformed, % of total | 40 | 40 |
| NG preheat temperature, °C (°F) | 476 (888) | 477 (890) |
| Oxygen-to-NG mass feed ratio | 0.45 | 0.44 |
| Oxygen preheat temperature, °C (°F) | 177 (350) | 177 (350) |
| Steam-to-NG molar ratio | 1.0 | 1.0 |
| Steam feed temperature, °C (°F) | 149 (300) | 260 (500) |
| Carbon loss, % of NG carbon | 0 | 0 |
| Raw syngas composition basis | Equilibrium | Equilibrium |
| SOFC feed gas methane content, mol% (dry) | 30.2 | 32.3 |
| Raw Syngas Cooler | | |
| Technology | Tube-in-shell | Tube-in-shell |
| Number in parallel | 2 | 1 |
| Outlet temperature, °C (°F) | 149 (300) | 149 (1505) |

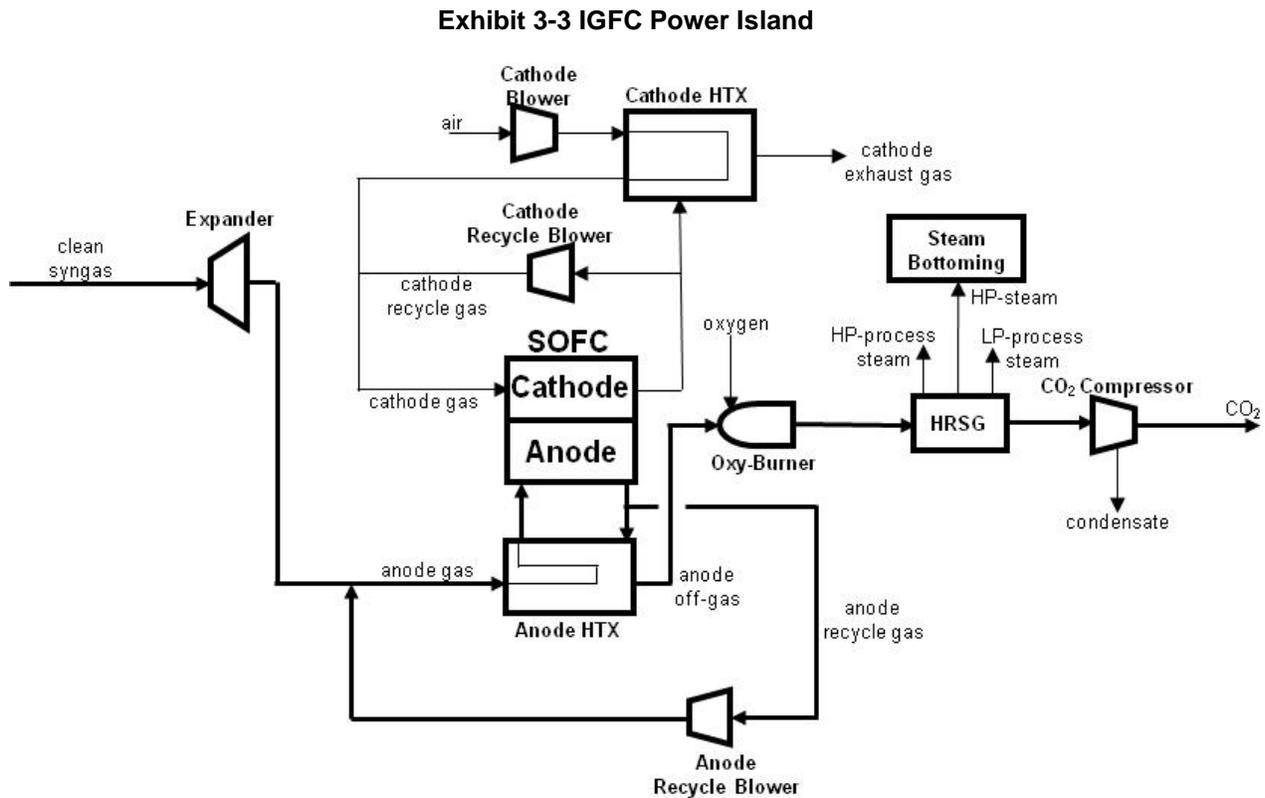

3.3 SOFC Power Island

The SOFC power island components are shown in the Exhibit 3-3 flow diagram. They consist of a natural gas expander, or a syngas expander that expands the syngas from its high-pressure condition down to the operating pressure of the fuel cell unit, the SOFC fuel cell unit with DC-

AC inverters, an anode off-gas oxy-combustor, a heat recovery steam generator that captures heat from the combusted anode off-gas, and a steam bottoming cycle. The SOFC fuel cell unit ancillary components consist of cathode air blowers, cathode heat exchangers that recuperatively heat the cathode air up to the fuel cell inlet temperature, cathode hot gas recycle blowers, and anode heat exchangers that recuperatively heat the anode gas up to the fuel cell inlet temperature, and anode hot gas recycle blowers. Hot gas blowers capable of operation at the required conditions of the anode and cathode recycle gas streams are currently under development [14].

The heat recovery steam generator produces low-pressure and high-pressure process steam, and high-pressure power steam for the subcritical steam bottoming cycle. The cooling water system uses a mechanical draft, wet cooling tower arrangement.

In Pathway 2, in which pressurized fuel cell operation is used, the cathode air is compressed to the pressurized fuel gas inlet pressure, and no cathode gas recycle is used. The cathode off-gas is expanded to atmospheric pressure to generate power to drive the cathode gas compressor. Anode gas recycle is accomplished using a syngas-driven jet pump in this pressurized case.

The major assumptions for the atmospheric-pressure SOFC power island are listed in Exhibit 3-4. In all of the study cases, it is assumed that the anode inlet gas to the fuel cell must have a total oxygen-to-carbon atomic ratio of at least 2.0 to avoid carbon deposition in the fuel cell. This constraint is satisfied by maintaining sufficiently high anode gas recycle, with the hot anode gas recycle increasing the water vapor content, and the associated oxygen-to-carbon atomic ratio in the anode inlet gas.

The anode off-gas is combusted using oxygen in an advanced oxy-combustor with excess oxygen limited to 1 mole percent. It is assumed that an anode off-gas oxy-combustor can be developed that can operate stably with 1 mole percent excess oxygen.

Exhibit 3-4 Power Island Baseline Conditions and Assumptions

| | Pathway 1 | Pathway 2 |

Heat Recovery Steam generator and Steam Power Cycle

The Bituminous Baseline report [1] provides a detailed description of the HRSG and steam power cycle process configuration and equipment in typical IGCC and NGCC power plants. The HRSG and steam power cycle for the NGFC cases evaluated in this report are expected to be

similar in configuration and operating conditions to the comparable IGCC and NGCC systems. Only simplified simulation of the steam system was conducted in this evaluation, as described in Section 2.

3.4 CO₂ Dehydration and Compression Area

The oxy-combustion off-gas stream, after all heat recovery is completed, is compressed from its delivery pressure to a supercritical condition at 15.3 MPa (2215 psia) using four parallel multiple-stage, intercooled compressors. During compression, the CO₂ stream is dehydrated before each compression stage by water cooling and water knockout, and ultimately to a dewpoint of -40°C (-40°F) with a triethylene glycol system. The CO₂ is transported to the plant fence line and is sequestration ready. In its dry state it will contain about two to three mole percent oxygen. It is assumed that this will be acceptable, although it far exceeds the currently adopted criteria for CO₂ sequestration gas.

3.5 Accessory Electric Plant

The accessory electric plant consists of switchgear and control equipment, generator equipment, station service equipment, conduit and cable trays, and wire and cable. It also includes the main power transformer, all required foundations, and standby equipment.

3.6 Instrumentation and Control

An integrated plant-wide distributed control system (DCS) is provided. The DCS is a redundant microprocessor-based, functionally distributed control system. The control room houses an array of multiple video monitor (CRT) and keyboard units. The CRT/keyboard units are the primary interface between the generating process and operations personnel. The DCS incorporates plant monitoring and control functions for all the major plant equipment. The DCS is designed to be operational and accessible 99.5 percent of the time it is required (99.5 percent availability). The plant equipment and the DCS are designed for automatic response to load changes from minimum load to 100 percent. Startup and shutdown routines are manually implemented, with operator selection of modular automation routines available. The exception to this, and an important facet of the control system for gasification, is the critical controller system, which is a part of the license package from the gasifier supplier and is a dedicated and distinct hardware segment of the DCS.

This critical controller system is used to control the ATR process. The partial oxidation of the fuel feed and oxygen feed streams to form a syngas product is a stoichiometric, temperature- and pressure-dependent reaction. The critical controller utilizes a redundant microprocessor executing calculations and dynamic controls at 100- to 200-millisecond intervals. The enhanced execution speeds as well as evolved predictive controls allow the critical controller to mitigate process upsets and maintain the reactor operation within a stable set of operating parameters.

4 Pathway 1: Atmospheric-Pressure SOFC Pathway

The first pathway considered is that for the NGFC plant using atmospheric-pressure SOFC technology with external natural gas reforming, where Case 1-1 represents its baseline case. This baseline case is subject to both performance and cost modifications in subsequent Cases 1-2 through 1-9, representative of a pathway development scenario.

4.1 Case 1-1: Baseline Plant Description

Case 1-1 assesses the baseline NGFC plant for atmospheric-pressure SOFC technology. It uses a low-pressure, auto-thermal reformer (ATR) for external natural gas reforming, and it applies SOFC operating, performance, and cost specifications representing the current status of the developing SOFC technology. The high, cold gas efficiency of the ATR (90 percent), and the high methane content of its product SOFC fuel gas (30 mole percent at dry condition) promotes high plant efficiency and low cost.

A criterion for a maximum of 50 mole-percent water vapor in the anode gas has been set based on SOFC materials corrosion concerns. This limitation results in a maximum SOFC fuel utilization of only 75 percent.

With reference to the Exhibit 4-1 block flow diagram and the Exhibit 4-2 stream table, the Case 1-1 baseline plant is described. Natural gas (Stream 1), delivered to the plant at 500 psia, is first preheated, recouping heat from the hot syngas stream. This natural gas stream is expanded to the ATR inlet pressure of 20 psia before it is split into two streams, a 40 percent stream to be reformed (Stream 2), and a 60 percent stream to be mixed with the reformer syngas product.

The 40 percent stream is fed to the ATR mixed with steam (Stream 4) where it is partially combusted with oxidant (Stream 5) and reacts in a catalytic reactor zone to achieve complete reformation (Stream 7). The syngas mass rate issued from the ATR is about 24 percent of the syngas rate generated in a conventional IGCC plant with CCS having the same plant net generating capacity, and a single ATR train is used.

A conventional ASU generates oxidant (99.5 percent pure) for the ATR (Stream 5) as well as for the anode off-gas oxy-combustor (Stream 6). The ASU oxidant capacity is about 54 percent of the oxidant capacity of a conventional IGCC plant with CCS having the same plant net generating capacity as the Case 1-1 plant. A single ASU train is used.

The syngas mixed with the remaining natural gas (Stream 8) comprises the SOFC fuel gas. There are six parallel SOFC sections in the plant, each containing a single cathode heat exchanger, anode heat exchanger, cathode air blower, cathode recycle gas blower, and anode gas recycle blower.

The SOFC fuel gas stream is preheated through the anode heat exchanger and is mixed with recycled anode gas to achieve the anode inlet temperature (Stream 10). Air is boosted in pressure by the cathode air blower (Stream 12), is preheated through the cathode heat exchanger, and is mixed with recycled cathode gas to achieve the cathode inlet temperature (Stream 13). The cathode inlet gas provides the oxygen needed for the SOFC oxidation reactions, and provides cooling of the cells to maintain temperatures at an acceptable distribution. The cell cooling is aided by the reforming of methane throughout the cells, reducing the required flow of cathode air.

The cathode off-gas passes through the cathode heat exchanger and is then vented. The HRSG shown following Stream 14 is not used in Case 1-1. The anode off-gas (Stream 11) is combusted across the oxy-combustor, generating a hot combustion gas (Stream 15) having 1 percent excess oxygen content. The HRSG raises high-pressure steam for the steam bottoming cycle, 50 psia steam for the ATR, and low-pressure steam for the auxiliary processing needs.

The NGFC steam plant has a capacity of about 51 percent of the steam plant in a conventional IGCC plant with CCS having the same plant net generating capacity. The NGFC steam plant has a capacity of about 71 percent of the steam plant in a conventional NGCC plant with CCS having the same plant net generating capacity. A single train configuration of oxy-combustor, HRSG and steam power system is used in the plant.

The cooled combustion gas is dehydrated and compressed to 2215 psia to generate the plant's CO₂ product for sequestration (Stream 16). The CO₂ sequestration rate is at a capacity of about 42 percent of that of a conventional IGCC plant with CCS having the same plant net generating capacity. The NGFC plant CO₂ sequestration rate is about 90 percent of that of a conventional NGCC plant with CCS having the same plant net generating capacity. Four parallel CO₂ compression trains are used in the Case 1-1 plant.

4.2 Case 1-1: Baseline Plant Performance

The Case 1-1 baseline plant power summary is shown in Exhibit 4-4. The dominant power generator in the plant is the SOFC system. Because the SOFC total fuel utilization is only 75 percent in Case 1-1, the steam bottoming cycle generates a relatively large amount of power also, about 20 percent of the plant's gross output. The dominant auxiliary loads in the plant are the ASU air compression, the CO₂ compression, and the cathode air and recycle gas blowers. The plant efficiency is 53.3 percent (HHV). The total plant auxiliary power is 10.8 percent of the gross generating capacity of the plant.

Exhibit 4-4 provides more perspective on the stream flows through the plant. All mass flows are indicated in this simplified process schematic relative to the total natural gas feed rate. Pressures are also indicated for some key streams. The mass flows around the ASU and the ATR are small compared to the mass flows around the SOFC system. The cathode-side flows are very large relative to the natural gas flow, being as much as 27 times the natural gas flow. The CO₂ product stream flow is 2.7 times the natural gas flow.

Likewise, Exhibit 4-5 provides perspective on the energy stream flows within the Case 1-1 plant. It shows the major fuel-stream flows relative to the natural gas feed stream fuel-energy content. The diagram also indicates component auxiliary power, temperatures of some key streams, and heat transfer duties of the major plant heat exchanger units.

96 percent of the natural gas feed stream fuel-energy passes to the SOFC system in the anode gas feed stream. Because of the need to operate with 75 percent SOFC total fuel utilization, 28.2 percent of the natural gas feed fuel-energy passes on to the oxy-combustor. The cathode heat exchanger has a particularly high duty at 29 percent of the total natural gas fuel-energy content. Recycling of cathode gas significantly reduces the size and cost of this heat exchanger.

The SOFC voltage is indicated on the diagram as being 0.83 volts. The Nernst potential at the anode outlet condition is 0.91 volts, at the anode inlet condition is 0.97 volts, and the average Nernst is 0.94 volts.

Exhibit 4-6 and Exhibit 4-7 tabulate the HP- and LP-steam balances for the plant. The oxy-combustor HRSG generates all of the HP- and LP-steam requirements for the plant.

Exhibit 4-8 shows the overall water balance for Case 1-1. Water demand represents the total amount of water required for the plant. Some water is recovered within the plant, and is re-used as internal recycle. The difference between demand and recycle is raw water withdrawal. Raw water withdrawal is defined as the water removed from the ground or diverted from a surface-water source for use in the plant and was assumed to be provided 50 percent by a Publicly Owned Treatment Works (POTW) and 50 percent from groundwater. The difference between water withdrawal and process water discharge is defined as water consumption. Cooling tower makeup is the dominant water demand in the plant. The recovery of condensate from the CO₂ exit stream and the high plant efficiency result in relatively small water consumption.

The carbon balance for the plant is shown in Exhibit 4-9 for Case 1-1. The only carbon input to the plant consists of carbon in the natural gas. About 99.9 percent of the natural gas carbon content is captured in the CO₂ sequestration stream.

Air emissions, in Exhibit 4-10, are nearly zero for Case 1-1 because all of the controlled species remaining in the very clean syngas are co-sequestered with the CO₂ product. The only CO₂ emission is from vented exhaust streams from condensate processing, with the total carbon removal exceeding 99 percent. The NO_x emitted by the anode off-gas oxy-combustor will be inherently low and is assumed to meet CO₂ sequestration requirements.

Exhibit 4-3 Case 1-1 Baseline Plant Power Summary (100 Percent Load)

| POWER SUMMARY | |
|--|------------------|

4.3 Case 1-1: Baseline Plant Cost Results

Capital cost estimates for Case 1-1 are broken down in Exhibit 4-11. The SOFC power island, at 524 \$/kW, represents 43 percent of the total plant cost. The SOFC units cost 77 percent of the SOFC power island. The cathode heat exchanger at 54 \$/kW is also a significant power island cost. The next highest capital costs in the plant are those of the ASU and the ATR systems, with the steam bottoming cycle and its related water systems also being significant.

The plant operating and maintenance costs, and the first-year cost-of-electricity (COE) for Case 1-1 are displayed in Exhibit 4-12 and Exhibit 4-13. These cost results yield an estimate for the avoided CO₂ cost of 29.6 \$/ton CO₂, relative to the conventional PC power plant with supercritical steam and without CCS.

The dominant cost factor in the COE is the cost of natural gas. The Exhibit 4-13 COE is based on a natural gas price of 6.55 \$/MMBtu. Exhibit 4-14 lists the Case 1-1 COE as a function of the price of natural gas over the range of 4.0 to 12.0 \$/MMBtu. As the price of natural gas triples, the COE rises by 175 percent.

4.4 Pathway 1 Results

The pathway variations from the Case 1-1 baseline plant include cases where only cost is modified by the pathway step (Cases 1-2, 1-4, 1-5, 1-7, and 1-9) due to reduced cell degradation rate, increased plant availability, and reduced cost of the SOFC stack. Other cases (Case 1-3, 1-6, and 1-8) incorporate pathway steps that impact both the plant performance and cost through reduced cell overpotential, increased inverter efficiency, and improved cell materials.

Exhibit 4-15 displays the major results for all of the Pathway 1 steps. The tabulation shows a climb in the plant efficiency and a reduction in the plant cost, with the greatest benefits resulting from reduced cell degradation rate (Case 1-2), reduced cell overpotential (Case 1-3), and improved cell materials allowing 90 percent fuel utilization (Case 1-8). Across the total pathway the COE is reduced by 19.1 \$/MWh, and the plant efficiency increases 8.3 percentage-points.

4.5 Case 1-8: Plant Description

Case 1-8 assumes the development of cell materials that tolerate high water vapor content (62 mole percent) and can thus operate at a high fuel utilization of 90 percent. Because this represents a major advancement in technology, with large modifications in plant characteristics, the details of Case 1-8 are presented. The block flow diagram is identical for all of the Pathway 1 steps, and only the stream table is presented for Case 1-8.

With reference to the Exhibit 4-1 block flow diagram and the Exhibit 4-16 stream table, the Case 1-8 plant is described. As in the baseline plant (Case 1-1), natural gas (Stream 1), delivered to the plant at 500 psia, is first preheated, recouping heat from the hot syngas stream. This natural gas stream is expanded to the ATR inlet pressure of 20 psia before it is split into two streams, a 40 percent stream to be reformed (Stream 2), and a 60 percent stream to be mixed with the reformer syngas product.

The 40 percent stream is fed to the ATR mixed with steam (Stream 4) where it is partially combusted with oxidant (Stream 5) and reacts in a catalytic reactor zone to achieve complete reformation (Stream 7). The syngas mass rate issued from the ATR is about 20 percent of the syngas rate generated in a conventional IGCC plant with CCS having the same plant net generating capacity, and a single ATR train is used.

A conventional ASU generates oxidant (99.5 percent pure) for the ATR (Stream 5) as well as for the anode off-gas oxy-combustor (Stream 6). The ASU oxidant capacity is about 30 percent of the oxidant capacity of a conventional IGCC plant with CCS having the same plant net generating capacity as the Case 1-1 plant. A single ASU train is used.

The syngas mixed with the remaining natural gas (Stream 8) comprises the SOFC fuel gas. There are eight parallel SOFC sections in the plant, each containing a single cathode heat exchanger, anode heat exchanger, cathode air blower, cathode recycle gas blower, and anode gas recycle blower.

The SOFC fuel gas stream is preheated through the anode heat exchanger and is mixed with recycled anode gas to achieve the anode inlet temperature (Stream 10). Air is boosted in pressure by the cathode air blower (Stream 12), is preheated through the cathode heat exchanger, and is mixed with recycled cathode gas to achieve the cathode inlet temperature (Stream 13). The cathode inlet gas provides the oxygen needed for the SOFC oxidation reactions, and provides cooling of the cells to maintain temperatures at an acceptable distribution. The cell cooling is aided by the reforming of methane throughout the cells, reducing the required flow of cathode air.

The cathode off-gas passes through the cathode heat exchanger and is then vented. The HRSG shown following Stream 14 is not used in Case 1-8. The anode off-gas (Stream 11) is combusted across the oxy-combustor, generating a hot combustion gas (Stream 15) having 1 percent excess oxygen content. The HRSG raises high-pressure steam for the steam bottoming cycle, 50 psia steam for the ATR, and low-pressure steam for the auxiliary processing needs.

The NGFC steam plant has a capacity of about 26 percent of that of a conventional IGCC plant with CCS having the same plant net generating capacity. The NGFC steam plant has a capacity of about 36 percent of that of a conventional NGCC plant with CCS having the same plant net generating capacity. A single train configuration of oxy-combustor, HRSG and steam power system is used in the plant.

The cooled combustion gas is dehydrated and compressed to 2215 psia to generate the plant's CO₂ product for sequestration (Stream 16). The CO₂ sequestration rate is at a capacity of about 37 percent of that of a conventional IGCC plant with CCS having the same plant net generating capacity. The NGFC plant CO₂ sequestration rate is about 80 percent of that of a conventional NGCC plant with CCS having the same plant net generating capacity. Four parallel CO₂ compression trains are used in the Case 1-8 plant.

4.6 Case 1-8: Plant Performance

The Case 1-8 plant power summary is shown in Exhibit 4-17. The dominant power generator in the plant is the SOFC system. Because the SOFC total fuel utilization is now 90 percent in Case 1-8, the steam bottoming cycle generates a smaller amount of power than in Case 1-1, about 12 percent of the plant's gross output. The dominant auxiliary loads in the plant remain the ASU air compression, the CO₂ compression, and the cathode air and recycle gas blowers, as in Case 1-1. The plant efficiency is 61.6 percent (HHV). The total plant auxiliary power is 8.8 percent of the gross generating capacity of the plant.

Exhibit 4-18 provides more perspective on the stream flows through the plant. All mass flows are indicated in this simplified process schematic relative to the total natural gas feed rate. Pressures are also indicated for some key streams. The mass flows around the ASU and the ATR are small compared to the mass flows around the SOFC system. The cathode-side flows are very large relative to the natural gas flow, being as much as 39 times the natural gas flow. The CO₂ product stream flow remains 2.7 times the natural gas flow.

Likewise, Exhibit 4-19 provides perspective on the energy stream flows within the Case 1-8 plant. It shows the major fuel-stream flows relative to the natural gas feed stream fuel-energy content. The diagram also indicates component auxiliary power, temperatures of some key streams, and heat transfer duties of the major plant heat exchanger units.

96 percent of the natural gas feed stream fuel-energy passes to the SOFC system in the anode gas feed stream. Because plant operates with 90 percent SOFC total fuel utilization, only 11.3 percent of the natural gas feed fuel-energy passes on to the oxy-combustor. The cathode heat exchanger has a particularly high duty at 41 percent of the total natural gas fuel-energy content. Recycling of cathode gas significantly reduces the size and cost of this heat exchanger.

The SOFC voltage is indicated on the diagram as being 0.87 volts. The Nernst potential at the anode outlet condition is 0.86 volts, at the anode inlet condition is 0.94 volts, and the average Nernst is 0.90 volts.

Exhibit 4-20 and Exhibit 4-21 tabulate the HP- and LP-steam balances for the plant. Again, as in Case 1-1, the oxy-combustor HRSG generates all of the HP- and LP-steam requirements for the plant.

Exhibit 4-22 shows the overall water balances for Case 1-8. Cooling tower makeup is the dominant water demand in the plant. The recovery of condensate from the CO₂ exit stream and the high plant efficiency result in relatively small water consumption, much smaller than in the baseline Case 1-1.

The carbon balance for the plant is shown in Exhibit 4-23 for Case 1-8. The only carbon input to the plant consists of carbon in the natural gas. About 99.9 percent of the natural gas carbon content is captured in the CO₂ sequestration stream.

Air emissions, in Exhibit 4-24, are nearly zero for Case 1-8 because all of the controlled species remaining in the very clean syngas are co-sequestered with the CO₂ product. The only CO₂ emission is from vented exhaust streams from condensate processing, with the total carbon removal exceeding 99 percent. The NO_x emitted by the anode off-gas oxy-combustor will be inherently low and is assumed to meet CO₂ sequestration requirements.

4.7 Case 1-8: Plant Cost Results

Capital cost estimates for Case 1-8 are broken down in Exhibit 4-25. The SOFC power island, at 411 \$/kW represents 43 percent of the total plant cost. The SOFC unit costs 74 percent of the SOFC power island. The cathode heat exchanger at 64 \$/kW is also a significant power island cost. The next highest capital costs in the plant are those of the ASU and the ATR systems, with the steam bottoming cycle and its related water systems also being significant.

The plant operating and maintenance costs, and the first-year cost-of-electricity (COE) for Case 1-8 are displayed in Exhibit 4-26 and Exhibit 4-27. These cost results yield an estimate for the avoided CO₂ cost of 7.9 \$/ton CO₂, relative to the conventional PC power plant with supercritical steam and without CCS. This is a great reduction in avoided cost compared to Case 1-1.

The dominant cost factor in the COE is the cost of natural gas. The Exhibit 4-27 COE is based on a natural gas price of 6.55 \$/MMBtu. Exhibit 4-28 lists the Case 1-8 COE as a function of the price of natural gas over the range of 4.0 to 12.0 \$/MMBtu. As the price of natural gas triples, the COE rises by 183 percent.

5 Pathway 2: Pressurized-SOFC Pathway

Pressurization of the SOFC stack provides the potential for enhanced power plant efficiency. But this comes with some greatly increased costs in the SOFC enclosures containing the pressurized stacks. The Case 2-1 baseline plant is subjected to a pathway development scenario in Cases 2-2, 2-3, and 2-4.

5.1 Case 2-1: Baseline Plant Description

The Case 2-1 baseline plant utilizes a high-pressure ATR system, and considers a configuration of an NGFC plant using a pressurized-SOFC unit. NGFC with pressurized-SOFC can be configured in two alternative arrangements:

1. The anode off-gas oxy-combustor is followed by hot gas expander power generation (expansion ratio about 18). A heat recovery steam generator (HRSG) produces steam for power generation, and the remaining, low-pressure, wet CO₂ stream is dried and compressed (compression ratio about 149).
2. The anode off-gas oxy-combustor is followed directly by a HRSG for steam bottoming power generation. The remaining, high-pressure, wet CO₂ stream is dehydrated and compressed (compression ratio about 8.4)

Sensitivity studies have shown that the first approach can result in slightly higher plant efficiencies than the second (about 1 percentage-point higher) with lower COE (about 1 \$/MWh lower), but the first configuration also requires the development of an advanced, high-temperature, CO₂-cooled turbine expander. The latter approach is expected to be the least complex and most effective approach and is utilized for this evaluation.

Preliminary sensitivity evaluations have been performed with the second approach to show that higher SOFC outlet pressure will result in slightly greater power plant efficiency, but with slightly greater COE. This increase in COE is due to the increasing cost of the cell stack containments at elevated pressures. This study has applied Pathway 2 with about the highest practical SOFC outlet pressure based on current gas turbine practice, 285 psia.

Case 2-1 is the baseline NGFC plant for pressurized SOFC technology. It uses a high-pressure, auto-thermal reformer (ATR) operated at 450 psia for external natural gas reforming, and it applies SOFC operating, performance, and cost specifications representing the current status of the developing SOFC technology, with the exception that the SOFC outlet pressure of 285 psia is far above current test experience. The high cold gas efficiency of the ATR (89 percent), and the high methane content of its product SOFC fuel gas (32 mole percent at dry condition) promotes high plant efficiency and low cost.

A criterion for a maximum of 50 mole-percent water vapor in the anode gas has been set based on SOFC materials corrosion concerns. This limitation results in a maximum SOFC fuel utilization of only 75.5 percent.

With reference to the Exhibit 5-1 block flow diagram and the Exhibit 5-2 stream table, the Case 2-1 baseline plant is described. Natural gas (Stream 1), delivered to the plant at 500 psia, is first split into two streams, a 40 percent stream to be reformed (Stream 2), and a 60 percent stream to be mixed with the reformer syngas product. The 40 percent stream to be reformed is preheated, recouping heat from the hot syngas stream. The 40 percent stream is fed to the ATR mixed with

steam (Stream 4) where it is partially combusted with oxidant (Stream 5) and reacts in a catalytic reactor zone to achieve complete reformation (Stream 7). The syngas mass rate issued from the ATR is about 21 percent of the syngas rate generated in a conventional IGCC plant with CCS having the same plant net generating capacity, and a single ATR train is used.

A conventional ASU generates oxidant (99.5 percent pure) for the ATR (Stream 5) as well as for the anode off-gas oxy-combustor (Stream 6). The ASU product oxidant streams are pressurized for the ATR (550 psia) and for the oxy-combustor (285 psia). The ASU oxidant capacity is about 52 percent of the oxidant capacity of a conventional IGCC plant with CCS having the same plant net generating capacity as the Case 2-1 plant. A single ASU train is used.

The syngas mixed with the remaining natural gas and expanded to the SOFC inlet pressure (Stream 8, at 290 psia) comprises the SOFC fuel gas. Note that a portion of the pressurized syngas bypasses the expander and is used as motive gas to operate the anode gas recycle jet pump. There are six parallel SOFC sections in the plant, each containing a single cathode heat exchanger, anode heat exchanger, cathode air compressor, cathode off-gas expander, and anode gas recycle jet pump.

The SOFC fuel gas stream is preheated through the anode heat exchanger and is mixed with recycled anode gas to achieve the anode inlet temperature (Stream 10). Air (Stream 12) is boosted in pressure by the cathode air compressor (290 psia), and is preheated through the cathode heat exchanger to achieve the cathode inlet temperature (Stream 13). There is no cathode gas recycle due to the technical challenge of boosting the pressure of hot, pressurized gas. The cathode inlet gas provides the oxygen needed for the SOFC oxidation reactions, and provides cooling of the cells to maintain temperatures at an acceptable distribution. The cell cooling is aided by the reforming of methane throughout the cells, reducing the required flow of cathode air.

The cathode off-gas passes through the cathode heat exchanger and is then expanded through the cathode gas expander before being vented. The anode off-gas (Stream 11) is combusted across the oxy-combustor, generating a hot, pressurized combustion gas (Stream 15, at 274 psia) having 1 percent excess oxygen content. The HRSG raises high-pressure steam for the steam bottoming cycle, 550 psia steam for the ATR, and low-pressure steam for the auxiliary processing needs.

The NGFC steam plant has a capacity of about 60 percent of that of a conventional IGCC plant with CCS having the same plant net generating capacity. The NGFC steam plant has a capacity of about 85 percent of that of a conventional NGCC plant with CCS having the same plant net generating capacity. A single train configuration of oxy-combustor, HRSG and steam power system is used in the plant.

The cooled combustion gas is dehydrated and compressed from 270 to 2215 psia in a two-stage, intercooled compressor to generate the plant's CO₂ product for sequestration (Stream 16). The CO₂ sequestration rate is at a capacity of about 37 percent of that of a conventional IGCC plant with CCS having the same plant net generating capacity. The NGFC plant CO₂ sequestration rate is about 81 percent of that of a conventional NGCC plant with CCS having the same plant net generating capacity. Four parallel CO₂ compression trains are used in the Case 2-1 plant.

5.2 Case 2-1: Baseline Plant Performance

The Case 2-1 baseline plant power summary is shown in Exhibit 5-3. The dominant power generator in the plant is the SOFC system. Because the SOFC total fuel utilization is only 75.5 percent in Case 2-1, the steam bottoming cycle generates a relatively large amount of power also, about 23 percent of the plant's gross output. The dominant auxiliary loads in the plant, in order, are the cathode air compression-expansion, the ASU air compression, the CO₂ compression, and the oxidant compression. The plant efficiency is 59.6 percent (HHV). The total plant auxiliary power is 11.9 percent of the gross generating capacity of the plant.

Exhibit 5-4 provides more perspective on the stream flows through the plant. All mass flows are indicated in this simplified process schematic relative to the total natural gas feed rate. Pressures are also indicated for some key streams. The mass flows around the ASU and the ATR are small compared to the mass flows around the SOFC system. The cathode-side flows are large relative to the natural gas flow, being as much as 18 times the natural gas flow. The CO₂ product stream flow is 2.7 times the natural gas flow.

Likewise, Exhibit 5-5 provides perspective on the energy stream flows within the Case 2-1 plant. It shows the major fuel-stream flows relative to the natural gas feed stream fuel-energy content. The diagram also indicates component auxiliary power, temperatures of some key streams, and heat transfer duties of the major plant heat exchanger units.

95.7 percent of the natural gas feed stream fuel-energy passes to the SOFC system in the anode gas feed stream. Because of the need to operate with 75.5 percent SOFC total fuel utilization, 30.3 percent of the natural gas feed fuel-energy passes on to the oxy-combustor. The cathode heat exchanger has a much smaller duty, at 8.5 percent of the total natural gas fuel-energy content, than in Case 1-1 because the compressed cathode air is at an elevated temperature due to its heat of compression.

The SOFC voltage is indicated on the diagram as being 0.94 volts. The Nernst potential at the anode outlet condition is 0.97 volts, at the anode inlet condition is 1.01 volts, and the average Nernst is 0.99 volts.

Exhibit 5-6 and Exhibit 5-7 tabulate the HP- and LP-steam balances for the plant. The oxy-combustor HRSG generates all of the HP- and LP-steam requirements for the plant.

Exhibit 5-8 shows the overall water balance for Case 2-1. Cooling tower makeup is the dominant water demand in the plant. The recovery of condensate from the CO₂ exit stream and the high plant efficiency result in relatively small water consumption.

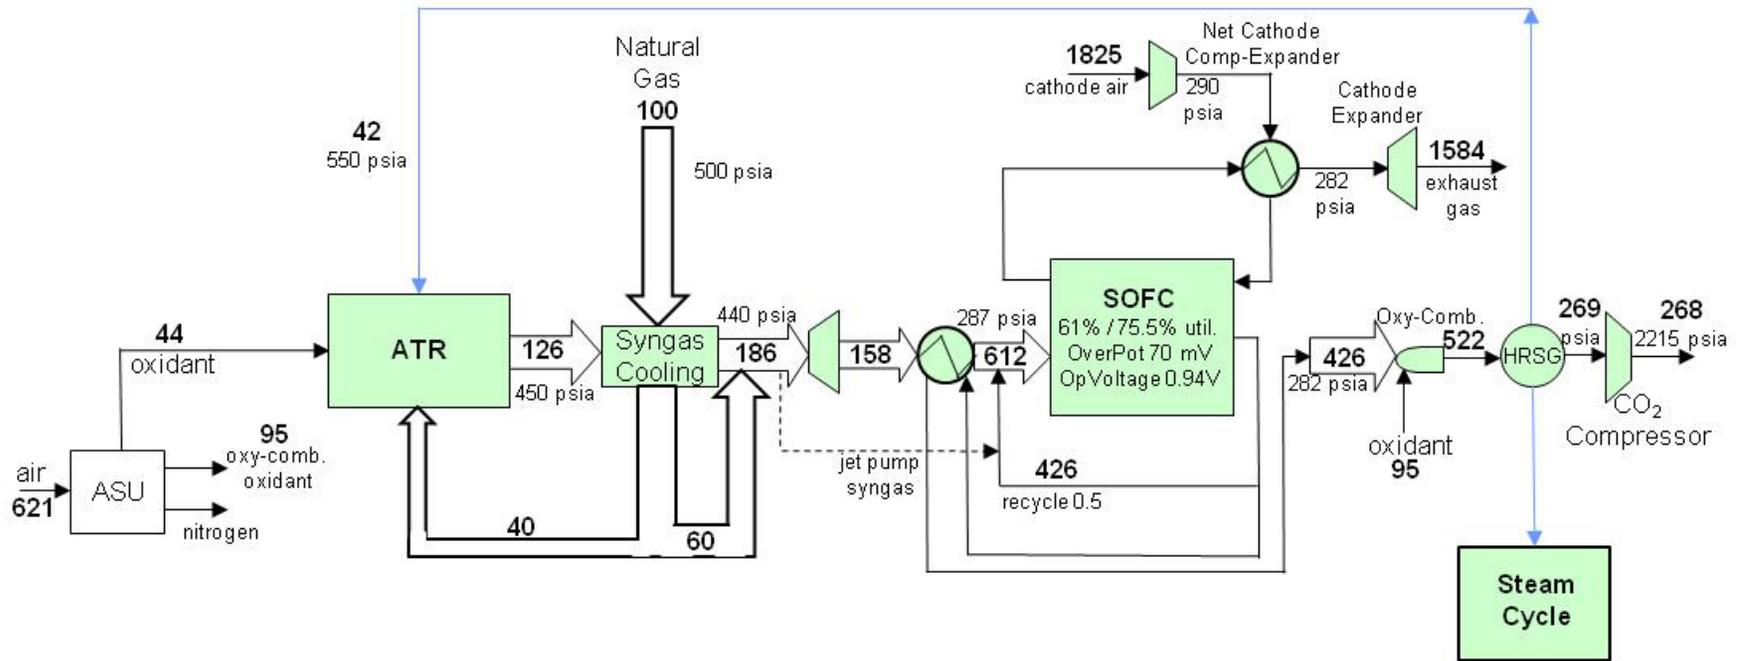

The carbon balance for the plant is shown in Exhibit 5-9 for Case 2-1. The only carbon input to the plant consists of carbon in the natural gas. About 98.4 percent of the natural gas carbon content is captured in the CO₂ sequestration stream. The CO₂ recovery value is smaller than in Case 1-1 because at high pressure more CO₂ is absorbed in the condensate water streams.

Air emissions, in Exhibit 5-10, are nearly zero for Case 2-1 because all of the controlled species remaining in the very clean syngas are co-sequestered with the CO₂ product. The only CO₂ emission is from vented exhaust streams from condensate processing, with the total carbon removal exceeding 98 percent. The NO_x emitted by the anode off-gas oxy-combustor will be inherently low and is assumed to meet CO₂ sequestration requirements.

5.3 Case 2-1: Baseline Plant Cost Results

Capital cost estimates for Case 2-1 are broken down in Exhibit 5-11. The SOFC power island, at 556 \$/kW represents 45 percent of the total plant cost. The SOFC units cost 80 percent of the SOFC power island. The other costs in the power island are relatively small. The next highest capital costs in the plant are those of the ASU and the ATR systems, with the steam bottoming cycle and its related water systems also being significant.

The plant operating and maintenance costs, and the first-year cost-of-electricity (COE) for Case 2-1 are displayed in Exhibit 5-12 and Exhibit 5-13. These cost results yield an estimate for the avoided CO₂ cost of 18.6 \$/ton CO₂, relative to the conventional PC power plant with supercritical steam and without CCS.

The dominant cost factor in the COE is the cost of natural gas. The Exhibit 5-13 COE is based on a natural gas price of 6.55 \$/MMBtu. Exhibit 5-14 lists the Case 2-1 COE as a function of the price of natural gas over the range of 4.0 to 12.0 \$/MMBtu. As the price of natural gas triples, the COE rises by 176 percent.

Exhibit 5-11 Case 2-1 Baseline Plant Capital Cost Breakdown

| Item/Description | TOTAL PLANT COST | |
|--|------------------|--------------|

5.4 Pathway 2 Results

The pathway variations from baseline Case 2-1 include cases where only cost is modified by the pathway step (Cases 2-2, and 2-3) due to improved plant availability, and reduced cost of the SOFC stack. One other case (Case 2-4) incorporates a pathway step that impacts both the plant performance and cost through improved cell materials.

Exhibit 5-15 displays the major results for all of the Pathway 2 steps. The tabulation shows a climb in the plant efficiency and a reduction in the plant cost, with the greatest benefits resulting from improved cell materials with 90 percent fuel utilization (Case 2-4).

5.5 Case 2-4: Plant Description

Case 2-4 assumes cell materials that tolerate high water vapor content (62 mole percent) and can operate at a fuel utilization of 90 percent. The block flow diagram in Exhibit 5-16 is identical for all of the Pathway 2 cases, and stream tables are presented only for the unique Case 2-4, having a dramatic change in characteristics from the other, prior cases.

With reference to the Exhibit 5-1 block flow diagram and the Exhibit 5-16 stream table, the Case 2-4 plant is described. Natural gas (Stream 1), delivered to the plant at 500 psia, is first split into two streams, a 40 percent stream to be reformed (Stream 2), and a 60 percent stream to be mixed with the reformer syngas product. The 40 percent stream to be reformed is preheated, recouping heat from the hot syngas stream. The 40 percent stream is fed to the ATR mixed with steam (Stream 4) where it is partially combusted with oxidant (Stream 5) and reacts in a catalytic reactor zone to achieve complete reformation (Stream 7). The syngas mass rate issued from the ATR is about 19.7 percent of the syngas rate generated in a conventional IGCC plant with CCS having the same plant net generating capacity, and a single ATR train is used.

A conventional ASU generates oxidant (99.5 percent pure) for the ATR (Stream 5) as well as for the anode off-gas oxy-combustor (Stream 6). The ASU product oxidant streams are compressed for the ATR (550 psia) and for the oxy-combustor (285 psia). The ASU oxidant capacity is about 30 percent of the oxidant capacity of a conventional IGCC plant with CCS having the same plant net generating capacity as the Case 2-1 plant. A single ASU train is used.

The syngas mixed with the remaining natural gas and expanded to the SOFC inlet pressure (Stream 8, at 290 psia) comprises the SOFC fuel gas. Note that a portion of the pressurized syngas bypasses the expander and is used as motive gas to operate the anode gas recycle jet pump. There are six parallel SOFC sections in the plant, each containing a single cathode heat exchanger, anode heat exchanger, cathode air compressor, cathode off-gas expander, and anode gas recycle jet pump.

The SOFC fuel gas stream is preheated through the anode heat exchanger and is mixed with recycled anode gas to achieve the anode inlet temperature (Stream 10). Air (Stream 12) is boosted in pressure by the cathode air compressor (290 psia), and is preheated through the cathode heat exchanger to achieve the cathode inlet temperature (Stream 13). There is no cathode gas recycle due to the technical challenge of boosting the pressure of hot, pressurized gas. The cathode inlet gas provides the oxygen needed for the SOFC oxidation reactions, and provides cooling of the cells to maintain temperatures at an acceptable distribution. The cell cooling is aided by the reforming of methane throughout the cells, reducing the required flow of cathode air.

The cathode off-gas passes through the cathode heat exchanger and is then expanded through the cathode gas expander before being vented. The anode off-gas (Stream 11) is combusted across the oxy-combustor, generating a hot, pressurized combustion gas (Stream 15, at 274 psia) having 1 percent excess oxygen content. The HRSG raises high-pressure steam for the steam bottoming cycle, 550 psia steam for the ATR, and low-pressure steam for the auxiliary processing needs.

The NGFC steam plant has a capacity of about 36 percent of that of a conventional IGCC plant with CCS having the same plant net generating capacity. The NGFC steam plant has a capacity of about 50 percent of that of a conventional NGCC plant with CCS having the same plant net

generating capacity. A single train configuration of oxy-combustor, HRSG and steam power system is used in the plant.

The cooled combustion gas is dehydrated and compressed to 2215 psia in a two-stage, intercooled compressor to generate the plant's CO₂ product for sequestration (Stream 16). The CO₂ sequestration rate is at a capacity of about 35 percent of that of a conventional IGCC plant with CCS having the same plant net generating capacity. The NGFC plant CO₂ sequestration rate is about 76 percent of that of a conventional NGCC plant with CCS having the same plant net generating capacity. Four parallel CO₂ compression trains are used in the Case 2-4 plant.

5.6 Case 2-4: Plant Performance

The Case 2-4 plant power summary is shown in Exhibit 5-17. The dominant power generator in the plant is the SOFC system. Because the SOFC total fuel utilization is 90 percent in Case 2-4, the steam bottoming cycle generates a relatively small amount of power also, about 14 percent of the plant's gross output. The dominant auxiliary loads in the plant, in order, are the cathode air compression-expansion, the ASU air compression, the oxidant compression, and the CO₂ compression. The plant efficiency is 63.6 percent (HHV). The total plant auxiliary power is 13.0 percent of the gross generating capacity of the plant.

Exhibit 5-18 provides more perspective on the stream flows through the plant. All mass flows are indicated in this simplified process schematic relative to the total natural gas feed rate. Pressures are also indicated for some key streams. The mass flows around the ASU and the ATR are small compared to the mass flows around the SOFC system. The cathode-side flows are large relative to the natural gas flow, being as much as 9 times the natural gas flow. The CO₂ product stream flow is 2.7 times the natural gas flow.

Likewise, Exhibit 5-19 provides perspective on the energy stream flows within the Case 2-4 plant. It shows the major fuel-stream flows relative to the natural gas feed stream fuel-energy content. The diagram also indicates component auxiliary power, temperatures of some key streams, and heat transfer duties of the major plant heat exchanger units.

95.7 percent of the natural gas feed stream fuel-energy passes to the SOFC system in the anode gas feed stream. Because the plant operates with 90 percent SOFC total fuel utilization, 11.8 percent of the natural gas feed fuel-energy passes on to the oxy-combustor. The cathode heat exchanger has a large duty, at 43.5 percent of the total natural gas fuel-energy content.

The SOFC voltage is indicated on the diagram as being 0.93 volts. The Nernst potential at the anode outlet condition is 0.93 volts, at the anode inlet condition is 1.00 volts, and the average Nernst is 0.96 volts.

Exhibit 5-20 and Exhibit 5-21 tabulate the HP- and LP-steam balances for the plant. The oxy-combustor HRSG generates all of the HP- and LP-steam requirements for the plant.

Exhibit 5-22 shows the overall water balances for Case 2-4. Cooling tower makeup is the dominant water demand in the plant. The recovery of condensate from the CO₂ exit stream and the high plant efficiency result in relatively small water consumption.

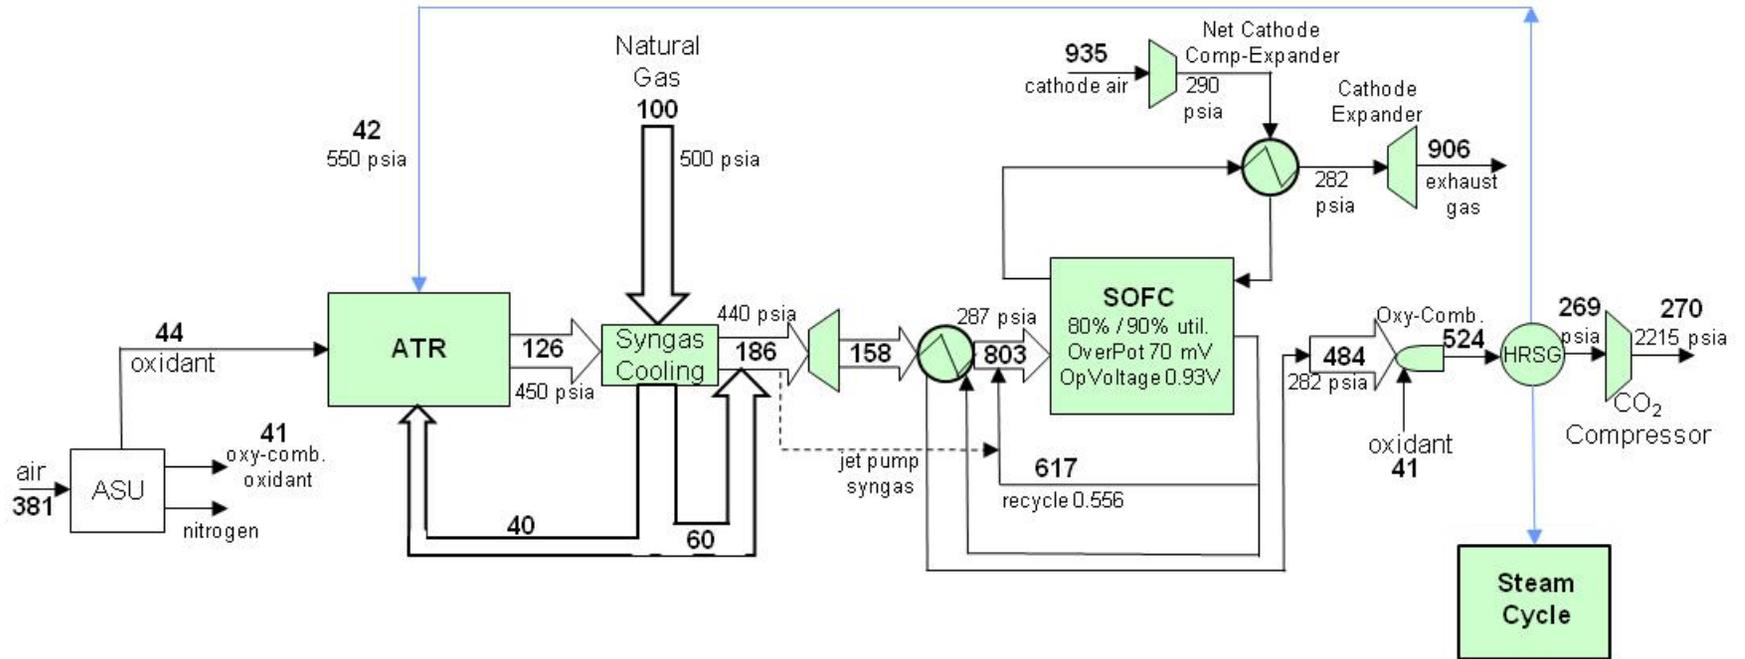

The carbon balance for the plant is shown in Exhibit 5-23 for Case 2-4. The only carbon input to the plant consists of carbon in the natural gas. About 98.4 percent of the natural gas carbon content is captured in the CO₂ sequestration stream. The CO₂ recovery value is smaller than in Case 1-1 because at high pressure more CO₂ is absorbed in the condensate water streams.

Air emissions, in Exhibit 5-24, are nearly zero for Case 2-4 because all of the controlled species remaining in the very clean syngas are co-sequestered with the CO₂ product. The only CO₂ emission is from vented exhaust streams from condensate processing, with the total carbon removal exceeding 98 percent. The NO_x emitted by the anode off-gas oxy-combustor will be inherently low and is assumed to meet CO₂ sequestration requirements.

Exhibit 5-17 Case 2-4 Plant Performance Summary (100 Percent Load)

| POWER SUMMARY | |
|--|------------------|
| GROSS POWER GENERATED, kWe | |
| SOFC Power | 540,902 |

5.7 Case 2-4: Plant Cost Results

Capital cost estimates for Case 2-4 are broken down in Exhibit 5-25. The SOFC power island, at 700 \$/kW represents 56 percent of the total plant cost. The SOFC units cost 68 percent of the SOFC power island. The other costs in the power island are relatively small. The next highest capital costs in the plant are those of the ASU and the ATR systems, with the steam bottoming cycle and its related water systems also being significant.

The plant operating and maintenance costs, and the first-year cost-of-electricity (COE) for Case 2-4 are displayed in Exhibit 5-26 and Exhibit 5-27. These cost results yield an estimate for the avoided CO₂ cost of 14.1 \$/ton CO₂, relative to the conventional PC power plant with supercritical steam and without CCS.

The dominant cost factor in the COE is the cost of natural gas. The Exhibit 5-27 COE is based on a natural gas price of 6.55 \$/MMBtu. Exhibit 5-28 lists the Case 2-4 COE as a function of the price of natural gas over the range of 4.0 to 12.0 \$/MMBtu. As the price of natural gas triples, the COE rises by 175 percent.

6 Pathway 3: SOFC with Internal Reforming

The Pathway 3 plant configuration is modified from Pathway 1, with the ATR being eliminated and the natural gas being fed directly to the SOFC unit. The SOFC stack is configured to contain appropriate catalytic reforming surfaces, arranged in such a way that the cooling of the stack, and the control of its temperature distribution through the cells result. This replacement has a large impact on all aspects of the plant design, the resulting plant performance, and the cost.

6.1 Case 3-1: Plant Description

Case 3-1 is assumed to be constrained by the water vapor limit of 50 mole percent in the anode gas, so that the fuel utilization can be no more than 83.4 percent. It applies atmospheric-pressure SOFC operating, performance, and cost specifications representing the current status of the developing SOFC technology. The internal reforming of the natural gas promotes high plant efficiency and low cost.

With reference to the Exhibit 6-1 block flow diagram and the Exhibit 6-2 stream table, the Case 3-1 plant is described. Natural gas (Stream 1), delivered to the plant at 50 psia, comprises the SOFC fuel gas. While a Stream 2 steam flow is indicated in the diagram, none is used in the actual case, with recycled anode gas providing sufficient water vapor. There are eight parallel SOFC sections in the plant, each containing a single cathode heat exchanger, anode heat exchanger, cathode air blower, cathode recycle gas blower, and anode gas recycle blower.

A conventional ASU generates oxidant (99.5 percent pure) for the anode off-gas oxy-combustor (Stream 4). The ASU oxidant capacity is about 23 percent of the oxidant capacity of a conventional IGCC plant with CCS having the same plant net generating capacity as the Case 3-1 plant. A single ASU train is used.

The SOFC fuel gas stream is preheated through the anode heat exchanger and is mixed with recycled anode gas to achieve the anode inlet temperature (Stream 6). Air is boosted in pressure by the cathode air blower (Stream 8), is preheated through the cathode heat exchanger, and is mixed with recycled cathode gas to achieve the cathode inlet temperature (Stream 9). The cathode inlet gas provides the oxygen needed for the SOFC oxidation reactions, and provides cooling of the cells to maintain temperatures at an acceptable distribution. The cell cooling is aided greatly by the reforming of methane throughout the cells, reducing the required flow of cathode air.

The cathode off-gas passes through the cathode heat exchanger and is then vented (Stream 10). The anode off-gas (Stream 7) is combusted across the oxy-combustor, generating a hot combustion gas (Stream 11) having 1 percent excess oxygen content. The HRSG raises high-pressure steam for the steam bottoming cycle, and low-pressure steam for the auxiliary processing needs.

The NGFC steam plant has a capacity of about 35 percent of that of a conventional IGCC plant with CCS having the same plant net generating capacity. The NGFC steam plant has a capacity of about 48 percent of that of a conventional NGCC plant with CCS having the same plant net generating capacity. A single train configuration of oxy-combustor, HRSG and steam power system is used in the plant.

The cooled combustion gas is dehydrated and compressed to 2215 psia to generate the plant's CO₂ product for sequestration (Stream 12). The CO₂ sequestration rate is at a capacity of about 35 percent of that of a conventional IGCC plant with CCS having the same plant net generating capacity. The NGFC plant CO₂ sequestration rate is about 76 percent of that of a conventional NGCC plant with CCS having the same plant net generating capacity. Four parallel CO₂ compression trains are used in the Case 3-1 plant.

6.2 Case 3-1: Plant Performance

The Case 3-1 plant power summary is shown in Exhibit 6-3. The dominant power generator in the plant is the SOFC system. Because the SOFC total fuel utilization is only 83 percent in Case 3-1, the steam bottoming cycle generates a relatively large amount of power also, about 14 percent of the plant's gross output. The dominant auxiliary loads in the plant are the CO₂ compression, the ASU air compression, and the cathode air and recycle gas blowers. The plant efficiency is 64.0 percent (HHV). The total plant auxiliary power is 7.6 percent of the gross generating capacity of the plant.

Exhibit 6-4 provides more perspective on the stream flows through the plant. All mass flows are indicated in this simplified process schematic relative to the total natural gas feed rate. Pressures are also indicated for some key streams. The mass flows around the ASU are small compared to the mass flows around the SOFC system. The cathode-side flows are very large relative to the natural gas flow, being as much as 17 times the natural gas flow. The CO₂ product stream flow is 2.7 times the natural gas flow.

Likewise, Exhibit 6-5 provides perspective on the energy stream flows within the Case 1-1 plant. It shows the major fuel-stream flows relative to the natural gas feed stream fuel-energy content. The diagram also indicates component auxiliary power, temperatures of some key streams, and heat transfer duties of the major plant heat exchanger units.

100 percent of the natural gas feed stream fuel-energy passes to the SOFC system in the anode gas feed stream. Because of the need to operate with 83 percent SOFC total fuel utilization, 21.3 percent of the natural gas feed fuel-energy passes on to the oxy-combustor. The cathode heat exchanger has a high duty at 18 percent of the total natural gas fuel-energy content. Recycling of cathode gas significantly reduces the size and cost of this heat exchanger.

The SOFC voltage is indicated on the diagram as being 0.84 volts. The Nernst potential at the anode outlet condition is 0.89 volts, at the anode inlet condition is 0.91 volts, and the average Nernst is 0.90 volts.

Exhibit 6-6 and Exhibit 6-7 tabulate the HP- and LP-steam balances for the plant. The oxy-combustor HRSG generates all of the HP- and LP-steam requirements for the plant.

Exhibit 6-8 shows the overall water balances for Case 3-1. Cooling tower makeup is the dominant water demand in the plant. The recovery of condensate from the CO₂ exit stream and the high plant efficiency result in relatively small water consumption.

The carbon balance for the plant is shown in Exhibit 6-9 for Case 3-1. The only carbon input to the plant consists of carbon in the natural gas. About 99.9 percent of the natural gas carbon content is captured in the CO₂ sequestration stream.

Air emissions, in Exhibit 6-10, are nearly zero for Case 3-1 because all of the controlled species remaining in the very clean syngas are co-sequestered with the CO₂ product. The only CO₂ emission is from vented exhaust streams from condensate processing, with the total carbon removal exceeding 99 percent. The NO_x emitted by the anode off-gas oxy-combustor will be inherently low and is assumed to meet CO₂ sequestration requirements.

6.3 Case 3-1: Plant Cost Results

The cost of the SOFC unit with reforming surfaces incorporated is not known, since the configuration has not been under developed for vendor projections. The maximum acceptable investment for the cells with internal reforming surfaces can be estimated so that the COE for Case 3-1 is the same as that for the comparable Case 1-6, with this case having all other SOFC specifications being the same as Case 3-1. A maximum stack cost of 440 \$/kW SOFC AC output results, compared to the current stack cost estimate of 140 \$/kW SOFC AC output. This means there is a large margin available for the stack cost with internal reforming surface incorporated and pursuing the development of this configuration is merited. The minimum COE for Case 3-1 results from the limiting situation where the stack cost is not increased by the addition of the internal reforming surfaces, with this COE being 63.3 \$/kWh.

For the purposes of sensitivity calculations, it is assumed that the stack cost with incorporated catalyst structures is 390 \$/kW SOFC output, representing a cost adder of 95 \$/kW for the catalyst structures.

6.4 Case 3-2: Plant Description

The Case 3-2 configuration is identical to Case 3-1, except that cell materials have been advanced so that high water vapor content can be tolerated and the SOFC unit can be operated with 90 percent utilization. It applies atmospheric-pressure SOFC operating, performance, and cost specifications representing the current status of the developing SOFC technology.

With reference to the Exhibit 6-1 block flow diagram and the Exhibit 6-11 stream table, the Case 3-2 plant is described. Natural gas (Stream 1), delivered to the plant at 50 psia, comprises the SOFC fuel gas. While a Stream 2 steam flow is indicated in the diagram, none is used in the actual case, with recycle anode gas providing sufficient water vapor. There are eight parallel SOFC sections in the plant, each containing a single cathode heat exchanger, anode heat exchanger, cathode air blower, cathode recycle gas blower, and anode gas recycle blower.

A conventional ASU generates oxidant (99.5 percent pure) for the anode off-gas oxy-combustor (Stream 4). The ASU oxidant capacity is only about 15 percent of the oxidant capacity of a conventional IGCC plant with CCS having the same plant net generating capacity as the Case 1-1 plant. A single ASU train is used.

The SOFC fuel gas stream is preheated through the anode heat exchanger and is mixed with recycled anode gas to achieve the anode inlet temperature (Stream 6). Air is boosted in pressure by the cathode air blower (Stream 8), is preheated through the cathode heat exchanger, and is mixed with recycled cathode gas to achieve the cathode inlet temperature (Stream 9). The cathode inlet gas provides the oxygen needed for the SOFC oxidation reactions, and provides cooling of the cells to maintain temperatures at an acceptable distribution. The cell cooling is aided greatly by the reforming of methane throughout the cells, reducing the required flow of cathode air.

The cathode off-gas passes through the cathode heat exchanger and is then vented (Stream 10). The anode off-gas (Stream 7) is combusted across the oxy-combustor, generating a hot combustion gas (Stream 11) having 1 percent excess oxygen content. The HRSG raises high-pressure steam for the steam bottoming cycle, and low-pressure steam for the auxiliary processing needs.

The NGFC steam plant has a capacity of only 26 percent of that of a conventional IGCC plant with CCS having the same plant net generating capacity. The NGFC steam plant has a capacity of only 35 percent of that of a conventional NGCC plant with CCS having the same plant net generating capacity. A single train configuration of oxy-combustor, HRSG and steam power system is used in the plant.

The cooled combustion gas is dehydrated and compressed to 2215 psia to generate the plant's CO₂ product for sequestration (Stream 12). The CO₂ sequestration rate is at a capacity of about 34 percent of that of a conventional IGCC plant with CCS having the same plant net generating capacity. The NGFC plant CO₂ sequestration rate is about 74 percent of that of a conventional NGCC plant with CCS having the same plant net generating capacity. Four parallel CO₂ compression trains are used in the Case 3-1 plant.

6.5 Case 3-2: Plant Performance

The Case 3-2 plant power summary is shown in Exhibit 6-12. The dominant power generator in the plant is the SOFC system. Because the SOFC total fuel utilization is 90 percent in Case 3-2, the steam bottoming cycle generates a relatively small amount of power, about 10 percent of the plant's gross output. The dominant auxiliary loads in the plant are the CO₂ compression, the ASU air compression, and the cathode air and recycle gas blowers. The plant efficiency is 65.9 percent (HHV). The total plant auxiliary power is only 6.8 percent of the gross generating capacity of the plant.

Exhibit 6-13 provides more perspective on the stream flows through the plant. All mass flows are indicated in this simplified process schematic relative to the total natural gas feed rate. Pressures are also indicated for some key streams. The mass flows around the ASU are small compared to the mass flows around the SOFC system. The cathode-side flows are very large relative to the natural gas flow, being as much as 25 times the natural gas flow. The CO₂ product stream flow is 2.7 times the natural gas flow.

Likewise, Exhibit 6-14 provides perspective on the energy stream flows within the Case 3-2 plant. It shows the major fuel-stream flows relative to the natural gas feed stream fuel-energy content. The diagram also indicates component auxiliary power, temperatures of some key streams, and heat transfer duties of the major plant heat exchanger units.

100 percent of the natural gas feed stream fuel-energy passes to the SOFC system in the anode gas feed stream. Because the plant operates with 90 percent SOFC total fuel utilization, 12.8 percent of the natural gas feed fuel-energy passes on to the oxy-combustor. The cathode heat exchanger has a high duty at 26 percent of the total natural gas fuel-energy content. Recycling of cathode gas significantly reduces the size and cost of this heat exchanger.

The SOFC voltage is indicated on the diagram as being 0.83 volts. The Nernst potential at the anode outlet condition is 0.87 volts, at the anode inlet condition is 0.90 volts, and the average Nernst is 0.88 volts.

Exhibit 6-15 and Exhibit 6-16 tabulate the HP- and LP-steam balances for the plant. The oxy-combustor HRSG generates all of the HP- and LP-steam requirements for the plant.

Exhibit 6-17 shows the overall water balances for Case 3-2. Cooling tower makeup is the dominant water demand in the plant. The recovery of condensate from the CO₂ exit stream and the high plant efficiency result in relatively small water consumption.

The carbon balance for the plant is shown in Exhibit 6-18 for Case 3-2. The only carbon input to the plant consists of carbon in the natural gas. About 99.9 percent of the natural gas carbon content is captured in the CO₂ sequestration stream.

Air emissions, in Exhibit 6-19, are nearly zero for Case 3-2 because all of the controlled species remaining in the very clean syngas are co-sequestered with the CO₂ product. The only CO₂ emission is from vented exhaust streams from condensate processing, with the total carbon

removal exceeding 99 percent. The NO_x emitted by the anode off-gas oxy-combustor will be inherently low and is assumed to meet CO₂ sequestration requirements.

6.6 Case 3-2: Plant Cost Results

The cost of the SOFC cell structure with reforming surfaces incorporated is not known, since the configuration has not been under developed for vendor projections. The maximum acceptable investment for the cells with internal reforming surfaces can be estimated so that the COE for Case 3-2 is the same as that for comparable Case 1-8, with this case having all other SOFC specifications being the same as Case 3-2. A maximum stack cost of 358 \$/kW SOFC AC output results, compared to the current stack cost of 140 \$/kW SOFC AC output. This means there is a large margin available for the stack cost with internal reforming surface incorporated and pursuing the development of this configuration is merited. The minimum COE for Case 3-2, for the limiting situation where the stack cost is not increased by the addition of the internal reforming surfaces, is 61.9 \$/kWh.

For the purposes of sensitivity calculations, it is assumed that the stack cost with incorporated catalyst structures is 390 \$/kW SOFC output, representing a cost adder of 95 \$/kW for the catalyst structures.
