1. ABSTRACT

A three-dimensional, three-phase, multiple-component numerical simulator was developed to investigate transport and growth of microorganisms in porous media and the impacts of microbial activities on oil recovery. The microbial activities modeled in this study included: (1) growth, retention, chemotaxis, and end product inhibition of growth, (2) the formation of metabolic products, and (3) the consumption of nutrients.

Major mechanisms for microbial enhanced oil recovery (MEOR) processes were modeled as follows: (1) improvement in sweep efficiency of a displacement process due to in situ plugging of highly-permeable production zones by cell mass or due to improved mobility control achieved by increasing the viscosity of the displacing fluid with a biopolymer, and (2) solubilization and mobilization of residual oil in porous media due to the reduction of the interfacial tension between oleic and aqueous phases by the production of a biosurfactant.

The numerical solutions for mathematical models involved two steps. The distributions of pressure and phase saturations were solved from continuity equations and Darcy flow velocities for the aqueous phase were computed. This was followed by the solution of convection-dispersion equations for individual components.

Numerical solutions from the proposed model were compared to results obtained from analytical equations, commercial simulators, and laboratory experiments. The comparison indicated that the model accurately quantified microbial transport and metabolism in porous media, and predicted additional crude oil recovery due to microbial processes.

2. EXECUTIVE SUMMARY

The goals of this project were to obtain quantitative information on the rate and extent of microbial growth and metabolism in porous materials, and to use this information to model microbial growth activity in porous materials and to predict oil recovery as a consequence of in situ microbial processes. These goals required the development of new experimental system and approaches to obtain the stoichiometric and kinetic information required to validate the mathematical models. Much of the work on the kinetics and stoichiometry of microbial growth and metabolism in porous materials was presented in our two previous reports.^{49,50} The information contained in these two report is summarized below.

2.1 Executive Summary of Previous Reports

During the first year, the metabolism and nutritional features of fermentative haloanaerobic bacteria was studied. Fermentative haloanaerobic bacteria were the most numerous organisms present in brine samples collected during a field pilot test of a microbial selective plugging process conducted in a hypersaline petroleum reservoir. Information about the metabolism and physiology of these bacteria was needed to mathematically model their growth and activity in sandstone cores. The fermentation of carbohydrates and the nutritional features of five haloanaerobic bacteria isolated from brine samples from the Vassar reservoir was studied. All of the isolates were strictly anaerobic and obligately halophilic, requiring a minimum of 6 to 9% (wt/vol) NaCl for growth in a complex medium. All of the isolates used carbohydrates, but most did not use amino acids or several of the tested aromatic compounds as energy sources. Glucose was

fermented to H₂, CO₂, ethanol, and acetate by all the strains. Formate was an additional product from glucose for strains VS-732 and VS-751. These studies showed that brines from a hypersaline oil reservoir contained a large population of anaerobic bacteria, and that these bacteria use a variety of fermentable carbohydrates to produce products such as acids, solvents, and gases that are potentially useful for enhanced oil recovery.

The metabolism of one of these strains, TTL-30, was studied in both liquid culture and in porous materials to determine whether the organism used a different pathway from glucose metabolism in the presence of a solid matrix, or whether the presence of a solid matrix influenced the kinetics of glucose metabolism. TTL-30 produced acetate, ethanol, hydrogen, and carbon dioxide from glucose when grown in liquid culture. The same end products were produced by TTL-30 when grown inside of core packed with sand, crushed sandstone, or crushed limestone. Less acetate and more ethanol were produced when TTL-30 was grown in the presence of crushed sandstone or limestone. The increased buffering capacity provided by the clays and carbonates present in these materials probably prevented the development of a low pH, which is prerequisite for solvent production. Acetate was exponentially produced by TTL-30 in the packs. Thus, the metabolic pathway used for glucose metabolism was the same whether or not the organisms were grown in the presence of a solid matrix, and the rate of metabolism in porous materials can be described by commonly mathematical expressions.

A simple porous chamber was designed to obtain statistically reliable data on the in situ rates of microbial growth, substrate consumption, and product formation. This system consisted of a small, plastic tube packed with sand or glass beads that was sealed at each end with rubber stopper. The porous system was used to study the kinetics of growth and the mode of penetration of strains of *Escherichia coli* through anaerobic, nutrient-saturated, sand-packed cores under static conditions. *E. coli* was used in these initial

experiments since its metabolism and growth kinetics are well described, and many mutants which lack important biological functions are available. The rate of growth of a chemotactic, motile strain of *E. coli*, RW262, was about 50% slower inside chambers than observed in liquid culture. The stoichiometry of galactose metabolism by strain RW262 was same in cores as in liquid culture. Without an applied advective force, RW262 grew exponentially and moved through chambers at a rate of about 0.1 m/d. Cells moved through chambers in a band-like fashion, as the front of cells had high cell concentrations (greater than 10^5 cells/ml). A motile, nonchemotactic mutant of *E. coli* penetrated cores faster than its chemotactic parental strain. The difference in penetration time between the chemotactic and nonchemotactic motile strains could be explained by differences in their modes of growth inside the chambers. The chemotactic strain grew and moved through cores in a bank-like fashion, as found with strain RW262. The nonchemotactic strain moved through chambers in a diffuse manner where the front of the moving cells had low cell concentrations ($\leq 10^3$ cells/ml), and where the appearance of cells in a section of the chamber was not necessarily followed by an increase in cell concentration in that section with time. The propagation of a nonmotile strain required a critical cell density in a section of the core before cells were detected in the next section. This suggested that the transport of nonmotile cells through porous material may occur by a physical displacement process where some of the progeny cells are forced into the less populated regions of the core.

The information obtained from studies on the metabolism of fermentative haloanaerobes and from studies on chemotactic migration and growth of bacteria through our simple porous experimental system was used to validate a mathematical model for microbial selective plugging.¹³ A three-phase, multipecies, one-dimensional model was developed to simulate bacterial transport, growth, and metabolism, and to predict the change in permeability as a result of in situ microbial growth. Convection-dispersion

equations and microbial growth kinetic equations were incorporated into the model to quantify the rate and extent of biomass production, product formation, and nutrient utilization during an MEOR process. Permeability reduction by the MEOR process was assumed to be due to pore plugging by the retention and growth of bacterial cells. The model was applied to static, unconsolidated sand-packed cores and sandstone core-flood experiments to simulate microbial movement, metabolite production, nutrient consumption coupled to microbial growth and to predict the net permeability reduction. Comparisons between numerical solutions and experimental results indicated that the model simulated the essential microbial kinetics of these laboratory experiments and can be extended to provide numerical predictions for the purpose of design and evaluation of MEOR field projects.

In the second year of the project, a new noninvasive method to measure microbial activity in porous materials was developed. The rate of in situ microbial activity was inferred from the rate of change in the pore pressure. The change in pore pressure was monitored continuously using an electronic transducer system. This method was used to determine the effect of pore size on the rate and extent of glucose degradation, and on the efficiency of substrate utilization by microorganisms. Porous chambers packed with different bead sizes, ranging from 75-150 to 710-1180 μm , had similar porosities (38%), but different pore sizes, ranging from 10 to 80 μm for chamber packed with the smallest to the largest glass bead size, respectively. The rate of penetration of both motile and nonmotile strains decreased with a decrease in pore size. Nutrient conditions that resulted in faster growth rates also resulted in faster penetration rates. The rate of hydrogen production, the final amount of the hydrogen produced, and the cell concentration decreased with a decrease in pore size. This study showed that pore size is an important factor governing the movement microorganisms through porous material, and suggested

that the reduced rate of penetration in chambers packed with the smallest pore sizes was due to a restriction of bacterial growth.

Newly developed non-linear regression models were applied to the hydrogen production data obtained in the above experiments. The integrated Monod model was successfully fit to the data from liquid-filled chambers that did not contain a solid matrix, and a maximum specific growth rate of 0.43 per hour was determined. The integrated Michaelis-Menton model more closely approximated that data from chambers where a solid matrix was present. The Michaelis-Menton model is used under conditions where microbial growth does not occur. The fact that Michaelis-Menton model more closely approximated the kinetics of product formation in the chambers than the Monod model did suggests that microbial growth was inhibited in some way by the presence of the porous media.

The fermentation of glucose by a halotolerant, polymer-producing bacterium, strain SP018, was studied in batch and continuous culture under aerobic and anaerobic conditions. Anaerobically, glucose was fermented to lactate, ethanol, carbon dioxide, plus an additional unidentified product. The yields of cells and polymer from glucose, and the maintenance coefficient were determined. Growth yield data indicated that the organism was not very efficient at conserving energy, or that the organism had a high maintenance requirement. The time course of glucose utilization was complex, and exponential decrease in glucose concentration as predicted from Monod kinetics was not observed. The pattern for polymer production was also complex since polymer production was observed at two different times during the course of the fermentation. Thus, predicting polymer production and glucose degradation by this organism will be difficult.

2.2 Executive Summary of Current Work

The three-phase, multispecies, one-dimensional model developed for microbial selective plugging was expended to a three-dimensional, three-phase, multi-component flow model that included mathematical expression for physical, chemical, and biological reactions in porous media. The model included component transport equations, microbial growth equations, equations for product formation (acids, gases, solvents, polymer, and biosurfactant) and nutrient consumption (glucose and ammonium nitrate), black oil formulations, and oil recovery equations. Transport of microorganisms, nutrients and metabolic products in the aqueous phase occurred by viscous, capillary, gravity, and dispersion forces. The model assumed that bacterial growth was limited by a single substrate, or by two substrates that are in low concentrations. Also, the production of certain end-product such as alcohol inhibited growth. Plugging of porous media by bacterial cells occurred as a consequence of two processes, the deposition of cells on pore surfaces which reduces porosity, and the entrapment of cells near pore throats which blocks fluid flow through these channels. A black oil simulation model was used to describe the simultaneous flow of oil, water, and gas phases in porous media during the microbially enhanced oil recovery (MEOR) processes. Finally, the MEOR simulator contained several mechanisms by which additional oil is recovered by microbial processes. These mechanisms included interfacial tension reduction, capillary desaturation, relative permeability alteration, and mobility control by biopolymers. The phase pressure and component transport equations derived for the MEOR simulator were a set of coupled, nonlinear, partial differential equations. These equations were transformed into discrete forms using finite differences, An implicit pressure, explicit saturation technique (IMPES)

was used to solve the pressure and phase saturations. This was followed by the solution of component transport equations.

The MEOR simulator was verified using analytical solutions and other simulators. Special cases regarding growth inhibition, chemotaxis, microbial plugging, biopolymer production, biosurfactant production, and gas production were used to test the simulator and investigate the mechanisms involved in MEOR processes. The simulation results showed that additional oil was recovered by the following processes: selective plugging, mobility control due to polymer production, and interfacial tension reduction due to biosurfactant production. Simulation of a microbial process involving gas production showed did not result in additional oil recovery. Apparently, the amount of gas produced during an MEOR process was insufficient to recover additional oil.

Finally, the MEOR simulator was used to model and predict the movement of chemotactic and nonchemotactic strains through sand-packed systems under nonflowing conditions, and the results obtained from MEOR core flood experiments using indigenous halophilic bacteria, an acid/solvent/gas-producing bacterium, and a biosurfactant-producing bacterium. The simulator accurately predicted the consumption of glucose and nitrate and the production of gases by indigenous halophilic bacteria in a Berea sandstone core. The proposed surface retention and pore throat plugging model accurately simulated the observed permeability reductions. Experimental studies showed that chemotactic bacteria move through porous materials in a band-like fashion, while nonchemotactic bacteria move in more diffusive manner. The MEOR simulator accurately simulated these types of bacterial movement. The production gas, acids, and solvents by *Clostridium acetobutylicum* was accurately predicted by the MEOR simulator. Finally, the simulator showed that oil recovery by a biosurfactant-producing bacterium was proportional to the amount of biosurfactant produced.

The transport, growth, and metabolism of microorganisms in porous materials was accurately quantified, and this information could be used to predict the amount of oil recovery from MEOR processes. Case studies showed that the major mechanisms for MEOR included improvements in sweep efficiency either by permeability reduction or by mobility control, and increase in the capillary number due to interfacial tension reductions resulting from biosurfactant production. Microbial gas production was not an effective reservoir-wide process for oil recovery.

3. INTRODUCTION

Primary production of crude oil is achieved by the depletion of the natural reservoir energy. Waterflooding as a secondary recovery technique is used to restore the reservoir pressure and displace the oil. After water breakthrough at producing wells, the water to oil ratio begins to increase until oil production is no longer economical. Unfortunately, up to two-thirds of the original oil-in-place remains in subsurface reservoirs after primary and secondary recovery processes reach their economic limits. Enhanced oil recovery (EOR) methods are needed to recover the remaining oil. The tertiary recovery techniques include steam injection, in-situ combustion, CO₂ flooding, and chemical flooding. All of these processes aim to improve the volumetric sweep efficiency, or to increase the capillary number. A cost-effective alternative to the above methods is to use microbes during waterflooding stage to improve oil recovery.

Microbially enhanced oil recovery (MEOR) processes involve injection of nutrients and perhaps microorganisms into the reservoir. Microbial growth and biopolymer production may lead to an improvement in the sweep efficiency of waterflood by permeability modification and/or increasing the viscosity of the displacing phase. Metabolic products such as surfactant, acids, and solvent may mobilize trapped crude oil by altering the surface characteristics of the rock or increasing capillary number.

The transport, growth, and metabolism of viable cells in subsurface formations are governed by complex physical, chemical, and biological phenomena. More research needs to be done before MEOR gains wide commercial acceptance. Associated with laboratory work, mathematical models are necessary to understand the mechanisms involved in the MEOR processes and to provide quantitative predictions for the design and evaluation of MEOR field projects.

The objective of the final part of this project was to develop a mathematical model that simulates transport and metabolism of microorganisms and nutrients in porous media and predicts additional oil recovery as results of those microbial processes. The mathematical formulations include component transport equations, the black oil model, microbial kinetics equations, a permeability reduction model, and models of oil recovery processes.

4. LITERATURE REVIEW

Here, a brief survey of the published literature on microbially enhanced oil recovery (MEOR) processes is presented. The scope of the review focuses on mechanisms involved in MEOR processes and mathematical modeling of MEOR processes.

4.1 Mechanisms

Permeability variation is one of the most significant factors affecting the degree of sweep efficiency and thus the performance of waterflooding processes. Many experimental studies¹⁻³ focused on testing the feasibility of a microbial process to selectively plug high permeability zones and thereby improve sweep efficiency and increase oil recovery. It has been shown (1) that viable bacteria and nutrients required for growth can be transported through sandstone cores, (2) that the in situ growth of bacteria results in significant reduction in permeability, (3) that the permeability reduction is selective for high permeability cores and improves sweep efficiency even under conditions where cross flow of fluids between regions occurs, and (4) that additional oil is recovered as a result of improved microscopic displacement and sweep efficiency.

Taylor *et al*^{4,5} conducted experimental and theoretical investigations to quantify the permeability reduction caused by enhanced biological growth in a porous media. It was observed that enhanced biological activities in sand column reactors can reduce the permeability significantly. An analytical relationship was established between biofilm thickness and the resulting decrease in permeability.

The formation of gases during MEOR treatments was reported in field trials⁶ as well as in laboratory experiments.^{7,8} It was proposed that the produced gas such as CO₂

can repressure reservoirs and swell crude oil to aid additional oil recovery. However, the observed increase in pressure and amount of gas produced are far below conditions required for miscibility. It appears that mechanisms of additional oil recovery in the presence of gases generated during microbial growth and metabolism are not clear.

Biosurfactants produced during growth and metabolism of bacteria may reduce interfacial tension between oil and water phases to mobilize residual oil trapped in porous media. Several anaerobic surfactants produced from species of *Bacillus* and *Clostridium* were reported.^{9,10} Micromodel studies⁷ with surfactant-producing microorganisms showed that emulsification of crude oil can occur during flow in a porous medium. Alcohol that microorganisms produce may act as a cosurfactant in microemulsion formulation.

Mobility control by high-viscosity biopolymer solutions may improve the sweep efficiency of the displacement process. It was reported¹¹ that a biopolymer produced anaerobically at 50 °C and a salinity of 8% can increase culture viscosity to 4 cp at a shear rate of 150 sec⁻¹.

2.2 Mathematical Simulation

Knapp *et al*¹² developed an one-dimensional mathematical model to describe the microbial plugging process. The model was used to investigate the impact of cellular growth and retention on the spatial and temporal reduction in permeability of porous media. It was assumed that the development of a stationary phase is due solely to biomass retention, and convective transport is the dominant mechanism for bacterial transport. The governing equations included a convection-dispersion equation for bacteria and nutrient transport and a mass conservation equation for stationary phase development.

Zhang *et al*¹³ reported an one-dimensional, multiple-component model to quantify biomass growth, product formation, substrate consumption involved in the MEOR processes. A modified Monod equation was used to describe bacterial growth assuming two substrates limited growth. Permeability reduction was assumed to be due to pore-surface retention and pore-throat plugging by bacterial cells. Thus permeability reduction was modeled as combination of porosity reduction and flow-efficiency decrease. The modeled components included biomass, carbon dioxide, nitrogen, acid, glucose, and ammonium nitrate.

Sarkar, *et al*¹⁴ developed an one-dimensional, two-phase, compositional numerical simulator to model the transport and growth of bacteria and oil recovery in MEOR process. The basic equations governing the transport of oil, water, bacteria, nutrient, and metabolites in porous media were component mass conservation equations. Permeability reduction was modeled using the effective medium theory. The oil recovery model is based on mechanisms such as interfacial tension reduction by biosurfactant and selective plugging by biomass. In their model, an implicit-pressure, explicit-concentration algorithm was used to solve pressure and mass conservation equations.

Islam¹⁵ presented a mathematical formulation to describe microbial transport in multidimensional porous media. In his formulation, multiphase flow equations were coupled with microbe and nutrient transport equations. Physical dispersion terms were neglected in the component transport equations. Since metabolic products were not included in this model, correlations which relate biomass to metabolites and their activities were defined. Numerical simulation runs were conducted to investigate bacterial plugging, interfacial tension reduction, carbon dioxide effects, etc. The results showed that surfactant-producing bacteria appeared to be most promising.

Chang *et al*^{16,17} incorporated the governing equations for microbial and nutrient transport into a three-dimensional, three-phase black oil model. Microbial activities simulated included net flux of microbes by convection and dispersion, microbial growth, decay, and chemotaxis, nutrient consumption, and deposition of microbes on rock grain surfaces. The alteration in rock wettability during microbial treatments was considered as the mechanism for oil recovery. Based on experimental results, empirical correlations between cell concentrations and the rock wettability, and between the rock wettability and residual phase saturations were established. In their simulator, the IMPES procedure was employed to solve pressure and saturations while a direct sparse matrix method was used to obtain solutions for component transport equations.

5. MATHEMATICAL MODELS

In this chapter, mathematical formulations for three-dimensional, three-phase, multiple-component flow with physical, chemical, and biological reactions in porous media have been developed under basic assumptions. The proposed models include component transport equations, the black oil model, microbial kinetics equations, a permeability reduction model, and models of oil recovery processes.

5.1 Assumptions

The following major assumptions have been made in developing the mathematical model for MEOR processes:

1. The three-dimensional reservoir is surrounded by impermeable zones.
2. The formation and fluids are slightly compressible.
3. The presence of three fluid phases (oil, water, and gas) is considered.
4. Bacteria, nutrients, and metabolic products are present in the aqueous phase.
5. Biogases generated from microbial growth and metabolism are modeled as in situ source terms for the gas phase.
6. The reservoir is isothermal.

5.2 Component Transport Equations

The multiple-component flow in porous media occurs as transport of microorganisms, nutrients, and metabolic products in the aqueous phase under the

influence of predominant forces such as viscous, capillary, gravity, and dispersion forces.

A general material balance equation for component k can be written as:

$$\frac{\partial}{\partial t} \left(\frac{\phi S_w}{B_w} C_k + \phi C_{ks} \right) = -\nabla \cdot \left(\frac{\bar{u}_t}{B_w} C_k \right) + \nabla \cdot \left(\frac{\phi S_w}{B_w} \bar{\bar{D}}_{kw} \nabla C_k \right) - \frac{q_w}{V_b} C_k + \frac{\phi S_w}{B_w} R_k \quad (5.1)$$

where, C_k and C_{ks} are flowing and sorbed mass concentrations at surface conditions for component k; ϕ is rock porosity; S_w , B_w , and q_w are saturation, formation volume factor, and volumetric injection/production rate for water phase, respectively; V_b is the rock bulk volume; \bar{u}_t is total flow velocity which is defined as the sum of Darcy and chemotactic velocities for bacteria and the Darcy velocity only for other components; $\bar{\bar{D}}_{kw}$ is the physical dispersion tensor for component k in the water phase; R_k represents the biological reaction rate for bacterial growth, product formation, or nutrient consumption.

The two terms in the left hand side of Eq (5.1) represent mass accumulation in aqueous phase and mass adsorption within the pore space for component k. The four terms in the right hand side of Eq (5.1) are convection, dispersion, injection/production, and biological reaction for component k, respectively. Component k in this equation could be bacteria (b), metabolic products (p), or substrates (s).

The total velocity \bar{u}_t in convection term of Eq (5.1) is defined as follows:

$$\bar{u}_t = \bar{u}_w + \bar{u}_c \quad \text{for bacteria} \quad (5.2)$$

$$\bar{u}_t = \bar{u}_w \quad \text{for metabolic products or substrates} \quad (5.3)$$

where, \bar{u}_w represents the Darcy velocity (flux) for water phase and \bar{u}_c is the chemotactic velocity for bacterial migration towards a richer nutrient supply.

Chemotaxis is defined as directed movement of a cell toward an attractant. Microorganisms can sense a nutrient-rich environment in all three dimensions. Darcy flow occurs due to pressure gradient while the chemotactic movement of bacteria is assumed to be proportional to an exponential change in substrate concentration:¹⁸

$$\bar{u}_c = K_c \nabla(\ln C_s) \quad (5.4)$$

where, K_c is chemotactic coefficient; C_s is substrate concentration.

Compared with convective flow, the chemotactic movement of bacteria is much slower. Thus chemotaxis becomes significant only under static conditions.

Physical dispersion phenomena is characterized by a full dispersion tensor:¹⁹

$$\bar{\bar{D}}_{kw} = \begin{bmatrix} D_{kw,xx} & D_{kw,xy} & D_{kw,xz} \\ D_{kw,yx} & D_{kw,yy} & D_{kw,yz} \\ D_{kw,zx} & D_{kw,zy} & D_{kw,zz} \end{bmatrix} \quad (5.5)$$

The elements of the dispersion tensor include both molecular diffusion and mechanical dispersion. For an isotropic medium, those elements are given as:¹⁹

$$D_{kw,xx} = \frac{D_k}{\tau} + \frac{(\alpha_{lw} - \alpha_{tw}) u_{wx}^2}{\phi S_w |\bar{u}_w|} + \frac{\alpha_{tw} |\bar{u}_w|}{\phi S_w} \quad (5.6)$$

$$D_{kw,yy} = \frac{D_k}{\tau} + \frac{(\alpha_{lw} - \alpha_{tw}) u_{wy}^2}{\phi S_w |\bar{u}_w|} + \frac{\alpha_{tw} |\bar{u}_w|}{\phi S_w} \quad (5.7)$$

$$D_{kw,zz} = \frac{D_k}{\tau} + \frac{(\alpha_{lw} - \alpha_{tw}) u_{wz}^2}{\phi S_w |\bar{u}_w|} + \frac{\alpha_{tw} |\bar{u}_w|}{\phi S_w} \quad (5.8)$$

$$D_{kw,xy} = D_{kw,yx} = \frac{(\alpha_{lw} - \alpha_{tw})}{\phi S_w |\bar{u}_w|} |u_{wx} u_{wy}| \quad (5.9)$$

$$D_{kw,xz} = D_{kw,zx} = \frac{(\alpha_{lw} - \alpha_{tw})}{\phi S_w |\bar{u}_w|} |u_{wx} u_{wz}| \quad (5.10)$$

$$D_{kw,yz} = D_{kw,zy} = \frac{(\alpha_{lw} - \alpha_{tw})}{\phi S_w |\bar{u}_w|} |u_{wy} u_{wz}| \quad (5.11)$$

where, D_k is molecular diffusion coefficient for component k in water phase; τ is tortuosity; α_{lw} and α_{tw} are longitudinal and transverse dispersivities; u_{wx} , u_{wy} , and u_{wz} are components of Darcy's velocity for water phase in X-, Y-, and Z-directions, respectively.

The norm of Darcy velocities for water phase is calculated by:

$$|\bar{u}_w| = \sqrt{u_{wx}^2 + u_{wy}^2 + u_{wz}^2} \quad (5.12)$$

5.3 Growth, Production, and Consumption Rates

Bacterial growth can be limited by either a single-substrate or a double-substrate medium. The growth may be inhibited by some metabolic end products such alcohol. A Monod type of specific growth rate with modifications of double-substrate limitation and product inhibition can be expressed as:²⁰

$$\mu_b = \mu_{bm} \left(\frac{C_{s1}}{K_{b/s1} + C_{s1}} \right) \left(\frac{C_{s2}}{K_{b/s2} + C_{s2}} \right) \left(\frac{K_i}{K_i + C_i} \right) \quad (5.13)$$

where, μ_{bm} is maximum specific growth rate; C_{s1} and C_{s2} are concentrations for substrates #1 and #2, respectively; $K_{b/s1}$ and $K_{b/s2}$ are saturation constants for substrates #1 and #2; K_i is the inhibition constant, and C_i is the concentration of inhibitor. If growth is controlled by only one substrate and growth inhibition is negligible, Eq (5.13) is reduced to a regular Monod model:

$$\mu_b = \mu_{bm} \frac{C_{s1}}{K_{b/s1} + C_{s1}} \quad (5.14)$$

Thus, biomass production rates for both the planktonic (R_b) and sessile (R_{bs}) bacterial phases can be computed by:

$$R_{bf} = \mu_b C_b \quad (5.15)$$

$$R_{bs} = \mu_b (\sigma \rho_{bsc}) \quad (5.16)$$

where, C_b is concentration for the flowing bacteria; σ is pore volume fraction occupied by bacteria sorbed on pore surfaces; ρ_{bsc} is biomass density at surface condition.

It is assumed that formation of metabolic end products occurs in both the planktonic and sessile phases of bacteria. A proposed empirical equation²¹ has been used to calculate production rate:

$$R_p = \mu_{pm} \left(\frac{C_s - C_{sc}}{K_{p/s} + C_s - C_{sc}} \right) (C_b + \sigma \rho_b) \quad \text{for } C_s > C_{sc} \quad (5.17)$$

where, μ_{pm} is maximum specific production rate for product p; $K_{p/s}$ is saturation constant for formation of product p by consumption of substrate s; C_{sc} is critical substrate concentration for product formation. Metabolic products modeled in this study are nitrogen, carbon dioxide, acid, alcohol, surfactant, and polymer.

Substrates are consumed to multiply cell mass, form metabolic products, and provide energy for maintenance. The rate of substrate utilization is related stoichiometrically to the rates of cell growth and product formation, and also related to maintenance energy:²⁰

$$R_s = -\frac{R_b}{Y_{b/s}} - \left(\sum_{p=1}^{NP} \frac{R_p}{Y_{p/s}} \right) - m_s (C_b + \sigma \rho_{bsc}) \quad (5.18)$$

where, R_s , R_b , and R_p are rates for substrate consumption, bacterial growth, and metabolic product formation, respectively; $Y_{b/s}$ and $Y_{p/s}$ are coefficients for biomass and product yields from substrate, respectively; m_s is the coefficient for maintenance energy provided by consuming substrate.

5.4 Adsorptions

Adsorption of microorganisms from aqueous suspension onto pore surfaces is considered as the results of dynamic processes which are simultaneous particle exchanges between the flowing and stationary phases of bacteria:²²

$$\frac{\partial C_{bs}}{\partial t} = R_r - R_d \quad (5.19)$$

where, C_{bs} is sorbed biomass per unit pore volume; R_r and R_d are retention and detachment rates for microorganisms, respectively.

The cell retention rate is proportional to biomass entering a given area " $|\bar{u}_w|C_b$ " and to the plugging capacity of the porous media " $1-\sigma$ ". The cell detachment rate is a function of the retained biomass " $\sigma\rho_b$ " and the shear force between the flowing and stationary phases " $|\nabla\Phi_w|$ ". Thus R_r and R_d can be expressed as:²²

$$R_r = K_r |\bar{u}_w| C_b (1 - \sigma) \quad (5.20)$$

$$R_d = K_d (\sigma\rho_b) |\nabla\Phi_w| \quad (5.21)$$

where, K_r and K_d are retention and detachment coefficients and Φ_w is the water-phase potential.

Adsorption of metabolic products or substrates is modeled by the Langmuir isotherm which assumes instantaneous equilibrium compared with the rate of convection and dispersion:²³

$$C_{ks} = \frac{a_k C_k}{1 + b_k C_k} \quad (5.22)$$

where, C_{ks} is the sorbed mass of component k per unit pore volume; a_k and b_k are Langmuir adsorption constants for component k; C_k is the mass concentration for component k in aqueous suspension.

5.5 Permeability Reduction Model

Plugging of porous media by bacterial cells occurs in such a way: (1) that cells may deposit on pore surfaces to reduce pore spaces available to fluids and (2) that cells may be trapped at or retained near pore throat to clog or bridge connections between channels through which fluids flow. Thus, permeability is modeled in terms of porosity reduction and flow-efficiency alteration:^{12,13,24}

$$\frac{K}{K_0} = f \left(\frac{\phi}{\phi_0} \right)^3 \quad (5.23)$$

where, K_0 and ϕ_0 are initial permeability and porosity, respectively; K and ϕ are the instantaneous permeability and porosity during MEOR processes; f is defined as a flow efficiency factor related to pore-throat plugging phenomena.

Porosity reduction is considered only due to biomass development on pore surfaces. Effects of other components on porosity reduction are neglected. The following equation determines instantaneous porosity in the presence of the sessile biomass (σ):¹²

$$\phi = \phi_0(1 - \sigma) \quad (5.24)$$

The accumulation of bacterial cells deposited on pore surface forms stationary biofilms (sessile bacteria). The sessile bacteria can grow by consumption of nutrients to occupy more pore spaces. A conservation equation states that sessile biomass development depends on bacterial retention (R_r), detachment (R_d), and growth (R_{bs}):^{13,22}

$$\frac{\partial(\sigma\rho_{\text{bsc}})}{\partial t} = R_r - R_d + R_{\text{bs}} \quad (5.25)$$

From a probabilistic point of view, the unplugging or flow efficiency factor (f) can be determined by estimating the likelihood of pore-throat plugging by biomass.²⁴

$$f = 1 - \frac{\int_{x_{\text{min}}}^{x_{\text{ct}}} g(x) dx}{\int_{x_{\text{min}}}^{x_{\text{max}}} g(x) dx} \quad (5.26)$$

where, x_{min} and x_{max} are minimum and maximum pore throat sizes; x_{ct} is critical pore throat size necessary for microbial plugging; $g(x)$ is the bimodal distribution function for pore throat sizes, which is given by:²⁵

$$g(x) = wg_1(x) + (1-w)g_2(x) \quad (5.27)$$

where, x is pore throat size; $g_1(x)$ and $g_2(x)$ are two unimodal distribution functions for pore throat sizes; w is weighting factor, $0 \leq w \leq 1$. $g_1(x)$ and $g_2(x)$ are expressed as:²⁵

$$g_1(x) = \frac{(x - x_{\text{min}})^{e_1 m_1} (x_{\text{max}} - x)^{m_1}}{\int_{x_{\text{min}}}^{x_{\text{max}}} (x - x_{\text{min}})^{e_1 m_1} (x_{\text{max}} - x)^{m_1} dx} \quad (5.28)$$

$$g_2(x) = \frac{(x - x_{\min})^{e_2 m_2} (x_{\max} - x)^{m_2}}{\int_{x_{\min}}^{x_{\max}} (x - x_{\min})^{e_2 m_2} (x_{\max} - x)^{m_2} dx} \quad (5.29)$$

where, e_1 , e_2 , m_1 , and m_2 are exponent parameters that control the shapes of distributions.

For computational convenience, the flow efficiency factor and pore-throat distribution functions can be expressed as dimensionless forms:

$$f = 1 - \frac{\int_{y_{\min}}^{y_{\text{crt}}} g(y) dy}{\int_{y_{\min}}^{y_{\max}} g(y) dy} \quad (5.30)$$

$$g(y) = w g_1(y) + (1 - w) g_2(y) \quad (5.31)$$

$$g_1(y) = \frac{(y - y_{\min})^{e_1 m_1} (y_{\max} - y)^{m_1}}{(x_{\max} - x_{\min}) \int_{y_{\min}}^{y_{\max}} (y - y_{\min})^{e_1 m_1} (y_{\max} - y)^{m_1} dy} \quad (5.32)$$

$$g_2(y) = \frac{(y - y_{\min})^{e_2 m_2} (y_{\max} - y)^{m_2}}{(x_{\max} - x_{\min}) \int_{y_{\min}}^{y_{\max}} (y - y_{\min})^{e_2 m_2} (y_{\max} - y)^{m_2} dy} \quad (5.33)$$

where, dimensionless variables are defined as:

$$y = \frac{x}{x_{\max} - x_{\min}} \quad (5.34)$$

$$y_{\text{crt}} = \frac{x_{\text{crt}}}{x_{\max} - x_{\min}} \quad (5.35)$$

$$y_{\min} = \frac{x_{\min}}{x_{\max} - x_{\min}} \quad (5.36)$$

$$y_{\max} = \frac{x_{\max}}{x_{\max} - x_{\min}} \quad (5.37)$$

An empirical expression has been proposed as a criterion to determine microbial plugging of pore throats:^{13,24}

$$\frac{x}{x_{\text{cb}}} \leq \alpha_e \left[1 - \exp \left(-\beta_e \frac{C_b |\bar{u}_w|}{\phi} - \gamma_e \sigma \right) \right] \quad (5.38)$$

where, x/x_{cb} is a ratio of pore-throat size to cell-body size; α_e , β_e , and γ_e are empirical parameters. Thus a critical pore-throat size (x_{crit}) necessary for clogging and bridging of pore throats by cells can be computed by:

$$x_{crit} = \alpha_e x_{cb} \left[1 - \exp \left(-\beta_e \frac{C_b |\bar{u}_w|}{\phi} - \gamma_e \sigma \right) \right] \quad (5.39)$$

where, the bacterial cell size, x_{cb} , is assumed to be uniform for all cells.

Eq.(5.39) states that the range of the pore throat (x_{crit}) plugged by cells increases as the planktonic bacterium concentration (C_b), the flow velocity ($|\bar{u}_w|/\phi$), and the sessile biomass fraction (σ) increase during MEOR processes.

5.6 Black Oil Model

Beside multiple-component transport equations, a multiphase transport model is developed to describe the simultaneous flow of oil, water, and gas phases in porous media during MEOR processes.

Consider flow of a single component c which is found in all three fluid phases, i.e. oil (o), water (w) and gas (g). Thus a typical mass balance equation for component c can be derived:²⁶

$$\frac{\partial}{\partial t} \left(\phi \sum_{\ell=o,w,g} x_{c\ell} \rho_{\ell} S_{\ell} \right) = -\nabla \cdot \left(\sum_{\ell=o,w,g} x_{c\ell} \rho_{\ell} \bar{u}_{\ell} \right) - \sum_{\ell=o,w,g} x_{c\ell} \tilde{m}_{\ell} \quad (5.40)$$

where, $x_{c\ell}$ is the mass fraction of component c in phase ℓ ; ρ_ℓ is phase density at reservoir conditions; S_ℓ is saturation for phase ℓ ; \bar{u}_ℓ is Darcy flux for phase ℓ ; \tilde{m}_ℓ is mass injection/production rate per unit rock bulk volume for phase ℓ .

For the black oil model, only three pseudocomponents will be considered: oil (o), water (w), and gas (g). Additional assumptions are made (1) that no phase transfer occurs between the water and oil, and (2) that gas can move in and out of the oil and water phases, but the oil and water are not allowed to vaporize into the gas phase. These assumptions lead to the following:

$$\begin{aligned}
 x_{oo} &= \frac{\rho_{osc}}{\rho_o B_o} & x_{wo} &= 0 & x_{go} &= \frac{\rho_{gsc} R_{so}}{\rho_o B_o} \\
 x_{ow} &= 0 & x_{ww} &= \frac{\rho_{wsc}}{\rho_w B_w} & x_{gw} &= \frac{\rho_{gsc} R_{sw}}{\rho_w B_w} \\
 x_{og} &= 0 & x_{wg} &= 0 & x_{gg} &= \frac{\rho_{gsc}}{\rho_g B_g}
 \end{aligned} \tag{5.41}$$

where, ρ_{osc} , ρ_{wsc} , and ρ_{gsc} are densities for oil, water, and gas phases at surface condition, respectively; B_o , B_w , and B_g are formation volume factors for oil, water, and gas phases; R_{so} and R_{sw} are solution gas-oil and gas-water ratios.

Using above relationships, the following continuity equations for multiphase flow can be obtained:

$$\frac{\partial}{\partial t} \left(\phi \frac{S_o}{B_o} \right) = \nabla \left(\frac{\bar{u}_o}{B_o} \right) - Q_o \quad \text{for oil} \quad (5.42)$$

$$\frac{\partial}{\partial t} \left(\phi \frac{S_w}{B_w} \right) = \nabla \left(\frac{\bar{u}_w}{B_w} \right) - Q_w \quad \text{for water} \quad (5.43)$$

$$\begin{aligned} \frac{\partial}{\partial t} \left[\phi \left(\frac{S_g}{B_g} + \frac{R_{so} S_o}{B_o} + \frac{R_{sw} S_w}{B_w} \right) \right] = \nabla \left(\frac{\bar{u}_g}{B_g} + \frac{R_{so} \bar{u}_o}{B_o} + \frac{R_{sw} \bar{u}_w}{B_w} \right) \\ - (Q_g + R_{so} Q_o + R_{sw} Q_w) \quad \text{for gas} \quad (5.44) \end{aligned}$$

where, Q_o , Q_w , and Q_g are volumetric flow rates per unit rock bulk volume for oil, water, and gas phases. These rates are defined as:

$$Q_\ell = \frac{\bar{m}_\ell}{\rho_\ell B_\ell} \quad \ell = o, w, g \quad (5.45)$$

Darcy fluxes for oil, water, and gas phases are given:

$$\bar{u}_\ell = - \frac{\bar{\bar{K}} K_{r\ell}}{\mu_\ell} \nabla \left(p_\ell - \rho_\ell \frac{g}{g_c} h \right) \quad (5.46)$$

where, $\bar{\bar{K}}$ is a diagonal permeability tensor; $K_{r\ell}$, μ_ℓ , p_ℓ , and ρ_ℓ are relative permeability, viscosity, pressure, and density for phase ℓ , respectively; g is the gravitational acceleration and g_c is a conversion constant; h is a positive distance below some horizontal

reference plane. The densities for oil, water, and oil phases are related to formation volume factor and gas solubilities by:

$$\rho_o = \frac{1}{B_o}(\rho_{osc} + R_{so}\rho_{osc}) \quad (5.47)$$

$$\rho_w = \frac{1}{B_w}(\rho_{wsc} + R_{sw}\rho_{wsc}) \quad (5.48)$$

$$\rho_g = \frac{\rho_{gsc}}{B_g} \quad (5.49)$$

The differences between phase pressures for oil-water and gas-oil systems are defined by capillary pressure concept:

$$p_{cow} = p_o - p_w \quad (5.50)$$

$$p_{cgo} = p_g - p_o \quad (5.51)$$

where, p_{cow} and p_{cgo} are capillary pressures for oil-water and gas-oil systems. Saturations for oil, water, and gas phases satisfy the following relationship:

$$S_o + S_w + S_g = 1 \quad (5.52)$$

Using IMPES formulation and combining Equations (5.42) through (5.52), a governing equation for the oil phase pressure (p) can be derived:²⁷

$$\phi C_t \frac{\partial p}{\partial t} = \sum_{\ell=o,w,g} \beta_\ell [\nabla(\Psi_\ell \nabla p) + GC_\ell - \frac{q_\ell}{V_b}] \quad (5.53)$$

where, C_t is total compressibility; β_ℓ is related to formation volume factor for phase ℓ ; Ψ_ℓ represents transmissibility for phase ℓ ; GC_ℓ is a term including gravity and capillary pressure for phase ℓ ; q_ℓ is volumetric injection or production rate for phase ℓ . All these terms are defined as:

$$C_t = C_r + C_o S_o + C_w S_w + C_g S_g \quad (5.54)$$

$$C_r = \frac{1}{\phi} \frac{\partial \phi}{\partial p} \quad (5.55)$$

$$C_o = -\frac{1}{B_o} \frac{\partial B_o}{\partial p} + \frac{B_g}{B_o} \frac{\partial R_{so}}{\partial p} \quad (5.56)$$

$$C_w = -\frac{1}{B_w} \frac{\partial B_w}{\partial p} + \frac{B_g}{B_w} \frac{\partial R_{sw}}{\partial p} \quad (5.57)$$

$$C_g = -\frac{1}{B_g} \frac{\partial B_g}{\partial p} \quad (5.58)$$

$$\beta_o = B_o - R_{so}B_g \quad (5.59)$$

$$\beta_w = B_w - R_{sw}B_g \quad (5.60)$$

$$\beta_g = B_g \quad (5.61)$$

$$\Psi_o = \frac{\bar{\bar{K}}K_{ro}}{B_o\mu_o} \quad (5.62)$$

$$\Psi_w = \frac{\bar{\bar{K}}K_{rw}}{B_w\mu_w} \quad (5.63)$$

$$\Psi_g = \frac{\bar{\bar{K}}K_{rg}}{B_g\mu_g} + R_{so}\Psi_o + R_{sw}\Psi_w \quad (5.64)$$

$$\bar{\bar{K}} = \begin{bmatrix} K_x & & \\ & K_y & \\ & & K_z \end{bmatrix} \quad (5.65)$$

$$GC_o = -\nabla[\Psi_o \nabla(\rho_o \frac{g}{g_c} z)] \quad (5.66)$$

$$GC_w = -\nabla[\Psi_w \nabla(\rho_w \frac{g}{g_c} z + p_{cow})] \quad (5.67)$$

$$GC_g = -\nabla[\Psi_g \nabla(\rho_g \frac{g}{g_c} z - p_{cgo})] + R_{so} GC_o + R_{sw} GC_w \quad (5.68)$$

$$q_o = Q_o V_b \quad (5.69)$$

$$q_w = Q_w V_b \quad (5.70)$$

$$q_g^* = Q_g V_b \quad (5.71)$$

$$q_g = q_g^* + R_{so} q_o + R_{sw} q_w \quad (5.72)$$

Once the oil phase pressure is determined from the equations above, the phase saturations for oil, water, and gas can be found by using the following equations:

$$\frac{\partial}{\partial t} (\phi \frac{S_o}{B_o}) = \nabla(\Psi_o \nabla p) + GC_o - \frac{q_o}{V_b} \quad (5.73)$$

$$\frac{\partial}{\partial t} (\phi \frac{S_w}{B_w}) = \nabla(\Psi_w \nabla p) + GC_w - \frac{q_w}{V_b} \quad (5.74)$$

$$S_g = 1 - S_o - S_w \quad (5.75)$$

5.7 Oil Recovery Model

In this section, mathematical representations are given to describe mechanisms for enhanced oil recovery by microbial activities. These mechanisms include interfacial tension

reduction, capillary desaturation, relative permeability alteration, and mobility control by biopolymer.

5.7.1 Interfacial Tension

The interfacial tension model used in this simulator is assumed to be a nonlinear correlation between interfacial tension and biosurfactant concentration:²⁸

$$\log(\sigma_{ow}) = \log(\sigma_{max}) - \left[\log\left(\frac{\sigma_{max}}{\sigma_{min}}\right) \right] \left(\frac{C_{6,max} - C_6}{C_{6,max} - C_{6,min}} \right)^{e_s} \quad (5.76)$$

where, σ_{ow} , σ_{min} , and σ_{max} are instantaneous, minimum, and maximum interfacial tensions between oleic and aqueous phases; C_6 , $C_{6,min}$, and $C_{6,max}$ are instantaneous, minimum, and maximum concentrations for biosurfactant, respectively; e_s is an exponent parameter.

5.7.2 Capillary Desaturation

Interfacial tension reduction increases the capillary number so that a portion of the residual phase becomes mobile. Thus the residual saturations for oil and water phases are modeled as a function of capillary number:²⁹⁻³¹

$$S_{\ell r} = S_{\ell r}^h + (S_{\ell r}^w - S_{\ell r}^h) T_{\ell 1} [\log(N_{c\ell}) + T_{\ell 2}] \quad S_{\ell r}^h \leq S_{\ell r} \leq S_{\ell r}^w \quad (5.77)$$

where, subscript ℓ represents oil or water phase; $S_{\ell r}^w$ and $S_{\ell r}^h$ are residual saturations for phase ℓ at low and high capillary numbers respectively; $N_{c\ell}$ is capillary number for phase

ℓ ; $T_{\ell 1}$ and $T_{\ell 2}$ are parameters related to the capillary desaturation curve (CDC). $T_{\ell 1}$ and $T_{\ell 2}$ are defined as:²⁹⁻³¹

$$T_{\ell 1} = \left[\log \left(\frac{N_{cl}^w}{N_{cl}^h} \right) \right]^{-1} \quad (5.78)$$

$$T_{\ell 2} = -\log(N_{cl}^h) \quad (5.79)$$

where, N_{cl}^w and N_{cl}^h are the low and high capillary numbers, respectively, which depend on fluid/rock properties such as wettability and pore size distribution.

The capillary number for phase p is computed by:³²

$$N_{cl} = \frac{|\bar{\bar{K}} \nabla \Phi_{\ell}|}{\sigma_{ow}} = \frac{\sqrt{K_x \frac{\partial \Phi_{\ell}}{\partial x} + K_y \frac{\partial \Phi_{\ell}}{\partial y} + K_z \frac{\partial \Phi_{\ell}}{\partial z}}}{\sigma_{ow}} \quad (5.80)$$

where, $\bar{\bar{K}}$ is diagonal permeability tensor; Φ_{ℓ} is potential for phase ℓ ; σ_{ow} is interfacial tension between oleic and aqueous phases, determined by Eq (5.75).

5.7.3 Capillary Pressure

A linear model is proposed to incorporate dependence of the oil-water capillary pressure (p_{cow}) on oil-water interfacial tension (σ_{ow}):²⁸

$$P_{\text{cow}} = P_{\text{cow}}^w \left(\frac{\sigma_{\text{ow}} - \sigma_{\text{min}}}{\sigma_{\text{max}} - \sigma_{\text{min}}} \right) \quad (5.81)$$

where, P_{cow}^w is oil-water capillary pressure at low capillary number.

5.7.4 Relative Permeability

The computed residual phase saturations from Eq.(5.77) are then used to determine phase relative permeabilities. Relative permeabilities for oil and water phases during MEOR processes are modeled using the following linear equations:^{15,28}

$$K_{\text{ro}}(S_o) = K_{\text{ro}}^w(S_o) + \frac{S_{\text{or}}^w - S_{\text{or}}}{S_{\text{or}}^w - S_{\text{or}}^h} [K_{\text{ro}}^h(S_o) - K_{\text{ro}}^w(S_o)] \quad (5.82)$$

$$K_{\text{rw}}(S_w) = K_{\text{rw}}^w(S_w) + \frac{S_{\text{wr}}^w - S_{\text{wr}}}{S_{\text{wr}}^w - S_{\text{wr}}^h} [K_{\text{rw}}^h(S_w) - K_{\text{rw}}^w(S_w)] \quad (5.83)$$

where, subscript w and h represent conditions at low and high capillary numbers, respectively. Relative permeabilities for oil and water phases at high capillary number are given by straight line models:¹⁵

$$K_{\text{ro}}^h = S_o \quad (5.84)$$

$$K_{\text{rw}}^h = S_w \quad (5.85)$$

5.7.5 Polymer-Rich Viscosity

Production of biopolymer during microbial growth and metabolism increases viscosity of the aqueous phase. For relatively small polymer concentration, the polymer-rich viscosity (μ_{pol}) can be approximately expressed as the following linear equation with water as the solvent:²⁸

$$\mu_{pol} = \mu_w + K_{pol}C_7 \quad (5.86)$$

where, μ_w is original water viscosity; K_{pol} is a constant; C_7 is biopolymer concentration.

5.7.6 Gases

Gases considered in this study include nitrogen and carbon dioxide. The contribution of generated biogases to enhanced oil recovery processes is modeled through source terms in the black oil model. Production rates for nitrogen and carbon dioxide are given as:

$$q_{g2} = \frac{R_2 V_{pw}}{\rho_{2sc} B_w} \quad (5.87)$$

$$q_{g3} = \frac{R_3 V_{pw}}{\rho_{3sc} B_w} \quad (5.88)$$

where, q_{g2} and q_{g3} are volumetric production rates at surface condition for nitrogen and carbon dioxide, respectively; R_2 and R_3 are mass generation rates per unit aqueous phase volume for nitrogen and carbon dioxide during growth and metabolism; V_{pw} is pore volume occupied by aqueous phase; ρ_{2sc} and ρ_{3sc} are densities at surface condition for nitrogen and carbon dioxide

Finally, the derived equations that describe MEOR processes are summarized in Tables 5.1 to 5.5.

Table 5.1 Basic MEOR Models

Variables	Equations
Components	$\frac{\partial}{\partial t} \left(\frac{\phi S_w}{B_w} C_k + \phi C_{ks} \right) = -\nabla \cdot \left(\frac{\bar{u}_t}{B_w} C_k \right) + \nabla \cdot \left(\frac{\phi S_w}{B_w} \bar{D}_{kw} \nabla C_k \right)$ $-\frac{q_w}{V_b} C_k + \frac{\phi S_w}{B_w} R_k$ <p>$k = 1, 2, 3, \dots, 10$</p>
Sessile Bacteria	$\frac{\partial(\sigma p_{isc})}{\partial t} = R_r - R_d + R_{ls}$
Pressure	$\phi C_t \frac{\partial p}{\partial t} = \sum_{\ell=o,w,g} \beta_\ell [\nabla \cdot (\Psi_\ell \nabla p) + GC_\ell - \frac{q_\ell}{V_b}]$
Saturations	$\frac{\partial}{\partial t} \left(\phi \frac{S_o}{B_o} \right) = \nabla \cdot (\Psi_o \nabla p_o) + GC_o - \frac{q_o}{V_b}$ $\frac{\partial}{\partial t} \left(\phi \frac{S_w}{B_w} \right) = \nabla \cdot (\Psi_w \nabla p_w) + GC_w - \frac{q_w}{V_b}$ $S_g = 1 - S_o - S_w$

Variables	Equations
Interfacial Tension	$\log(\sigma_{ow}) = \log(\sigma_{max}) - \left[\log\left(\frac{\sigma_{max}}{\sigma_{min}}\right) \right] \left(\frac{C_{6,max} - C_6}{C_{6,max} - C_{6,min}} \right)^{e_s}$
Capillary Numbers	$N_{cl} = \frac{ \bar{K} \nabla \Phi_\ell }{\sigma_{ow}} = \frac{\sqrt{K_x \frac{\partial \Phi_\ell}{\partial x} + K_y \frac{\partial \Phi_\ell}{\partial y} + K_z \frac{\partial \Phi_\ell}{\partial z}}}{\sigma_{ow}}$
Residual Satuations	$S_{lr} = S_{lr}^h + (S_{lr}^w - S_{lr}^h) T_{l1} [\log(N_{cl}) + T_{l2}]$
Relative Permeabilities	$K_{rl}(S_\ell) = K_{rl}^w(S_p) + \frac{S_{lr}^w - S_{lr}}{S_{lr}^w - S_{lr}^h} [K_{rl}^h(S_\ell) - K_{rl}^w(S_\ell)]$
Capillary Pressure	$p_{cow} = p_{cow}^w \left(\frac{\sigma_{ow} - \sigma_{min}}{\sigma_{max} - \sigma_{min}} \right)$
Viscosity for Polymer Solution	$\mu_{pol} = \mu_w + K_{pol} C_7$

6. NUMERICAL FORMULATION

The phase pressure and component transport equations derived in this study are a set of coupled, nonlinear partial differential equations. These equations are transformed to discrete forms using finite differences. An implicit pressure, explicit saturation (IMPES) technique is used to solve pressure and phase saturations. This is followed by the solution of the component transport equations.

6.1 Grid System

The spatial domain of interest is divided into a set of finite blocks. A block-centered grid system is selected for the finite difference formulation. The X- and Y-directions are defined as areal coordinates and the positive Z-direction is the vertical downward direction. In a natural ordering, blocks in an $N_x \times N_y \times N_z$ system (N_x blocks in each row, N_y blocks in each column, and N_z blocks in each plane) are numbered within a row, row by row and plane by plane in sequence. Figures 4.1 and 4.2 show the gridblock numbering for a $4 \times 3 \times 2$ grid system and the corresponding coefficient-matrix structure.

6.2 Pressure Equation Approximation

To approximate the partial differential equation by finite differences, a linear difference operator is defined as:

$$\Delta\Delta\Delta U = \Delta_x A \Delta_x U + \Delta_y A \Delta_y U + \Delta_z A \Delta_z U \quad (6.1)$$

where

$$\Delta_m A \Delta_m U = A_{m-1/2} (U_{m-1} - U_m) + A_{m+1/2} (U_{m+1} - U_m), \quad m = X, Y, Z \quad (6.2)$$

The pressure equation (5.53) is multiplied through by the bulk volume element $(V_b)_{xyz}$. Using the above definition of the linear operator, the resulting difference equation becomes:

$$\begin{aligned} \left(\frac{V_p^n C_t^n}{\Delta t} \right)_{xyz} (p^{n+1} - p^n)_{xyz} = & (B_o - R_{so} B_g)_{xyz}^n (\Delta A_o^n \Delta p^{n+1} + GCOT - q_o)_{xyz} + \\ & (B_w - R_{sw} B_g)_{xyz}^n (\Delta A_w^n \Delta p^{n+1} + GCWT - q_w)_{xyz} + \\ & (B_g)_{xyz}^n (\Delta A_g^n \Delta p^{n+1} + \Delta R_{so}^n A_o^n \Delta p^{n+1} + \Delta R_{sw}^n A_w^n \Delta p^{n+1} + \\ & GCGT - q_g)_{xyz} \end{aligned} \quad (6.3)$$

where, V_p is grid block pore volume; GCOT, GCWT, and GCGT are terms including gravity and capillary pressure. These terms are defined:

$$GCOT = -\Delta A_o^n \Delta (\rho_o h)^n \quad (6.4)$$

$$GCWT = -\Delta A_w^n \Delta (\rho_w h + p_{cow})^n \quad (6.5)$$

$$GCGT = -\Delta A_g^n \Delta (\rho_g h - p_{cgo})^n - R_{so}^n \Delta A_o^n \Delta (\rho_o h)^n - R_{sw}^n \Delta A_w^n \Delta (\rho_w h + p_{cow})^n \quad (6.6)$$

The gravity and capillary pressure terms in the X-direction can be expanded as:

$$\Delta_x A_\ell^n \Delta_x (\rho_\ell h)^n = A_{\ell,x-1}^n \left(\frac{\rho_{\ell,x-1}^n + \rho_{\ell,x}^n}{2} \right) (h_{x-1} - h_x) +$$

$$A_{\ell,x+1}^n \left(\frac{\rho_{\ell,x+1}^n + \rho_{\ell,x}^n}{2} \right) (h_{x+1} - h_x) \quad (6.7)$$

$$\Delta_x A_\ell^n \Delta_x (p_{c\ell\ell'})^n = A_{\ell,x-1}^n [(p_{c\ell\ell'})_{x-1}^n - (p_{c\ell\ell'})_x^n] +$$

$$A_{\ell,x+1}^n [(p_{c\ell\ell'})_{x+1}^n - (p_{c\ell\ell'})_x^n] \quad (6.8)$$

where, $\ell, \ell' = o, w, g$; $\ell \neq \ell'$. The gravity and capillary pressure terms in the Y- and Z-directions can be expanded in similar fashion.

Expanding the linear difference operators, the finite difference equation (6.3) can be further simplified:

$$AT_z p_{z-1}^{n+1} + AS_y p_{y-1}^{n+1} + AW_x p_{x-1}^{n+1} + AB_z p_{z+1}^{n+1} + AN_y p_{y+1}^{n+1} + AE_x p_{x+1}^{n+1} + E_{xyz} p_{xyz}^{n+1} = B_{xyz} \quad (6.9)$$

However, a perturbation in pressure over a time step Δt^{n+1} is δp_{xyz}^{n+1} and the pressure at the new time level can be expressed as:

$$p_{xyz}^{n+1} = p_{xyz}^n + \delta p_{xyz}^{n+1} \quad (6.10)$$

Obviously, solving for δp_{xyz}^{n+1} instead of p_{xyz}^{n+1} can enhance precision for numerical solutions. Substituting Eq. (6.10) into Eq. (6.9), the resulting finite difference equation is:

$$\begin{aligned}
 & AT_z \delta p_{z-1}^{n+1} + AS_y \delta p_{y-1}^{n+1} + AW_x \delta p_{x-1}^{n+1} + AB_z \delta p_{z+1}^{n+1} + \\
 & AN_y \delta p_{y+1}^{n+1} + AE_x \delta p_{x+1}^{n+1} + E_{xyz} \delta p_{xyz}^{n+1} = \hat{B}_{xyz}
 \end{aligned} \tag{6.11}$$

where

$$\begin{aligned}
 \hat{B}_{xyz} = & B_{xyz} - (AT_z p_{z-1}^n + AS_y p_{y-1}^n + AW_x p_{x-1}^n + \\
 & AB_z p_{z+1}^n + AN_y p_{y+1}^n + AE_x p_{x+1}^n + E_{xyz} p_{xyz}^n)
 \end{aligned} \tag{6.12}$$

Coefficients in Eq (6.9) are defined as follows:

$$\begin{aligned}
 AT_z = & [B_o + 0.5B_g (R_{so,z-1} - R_{so,z})]^n A_{o,z-1/2}^n + \\
 & [B_w + 0.5B_g (R_{sw,z-1} - R_{sw,z})]^n A_{w,z-1/2}^n + B_g^n A_{g,z-1/2}^n
 \end{aligned} \tag{6.13}$$

$$\begin{aligned}
 AS_y = & [B_o + 0.5B_g (R_{so,y-1} - R_{so,y})]^n A_{o,y-1/2}^n + \\
 & [B_w + 0.5B_g (R_{sw,y-1} - R_{sw,y})]^n A_{w,y-1/2}^n + B_g^n A_{g,y-1/2}^n
 \end{aligned} \tag{6.14}$$

$$AW_x = [B_o + 0.5B_g (R_{so,x-1} - R_{so,x})]^n A_{o,x-1/2}^n +$$

$$[B_{w,y} + 0.5B_g(R_{sw,x-1} - R_{sw,x})]^n A_{w,x-1/2}^n + B_g^n A_{g,x-1/2}^n \quad (6.15)$$

$$AB_z = [B_o + 0.5B_g(R_{so,z+1} - R_{so,z})]^n A_{o,z+1/2}^n +$$

$$[B_w + 0.5B_g(R_{sw,z+1} - R_{sw,z})]^n A_{w,z+1/2}^n + B_g^n A_{g,z+1/2}^n \quad (6.16)$$

$$AN_y = [B_o + 0.5B_g(R_{so,y+1} - R_{so,y})]^n A_{o,y+1/2}^n +$$

$$[B_w + 0.5B_g(R_{sw,y+1} - R_{sw,y})]^n A_{w,y+1/2}^n + B_g^n A_{g,y+1/2}^n \quad (6.17)$$

$$AE_x = [B_o + 0.5B_g(R_{so,x+1} - R_{so,x})]^n A_{o,x+1/2}^n +$$

$$[B_{w,x} + 0.5B_g(R_{sw,x+1} - R_{sw,x})]^n A_{w,x+1/2}^n + B_g^n A_{g,x+1/2}^n \quad (6.18)$$

$$E_{xyz} = -[AT_z + AS_y + AW_x + AB_z + AN_y + AE_x + \left(\frac{V_p^n C_t^n p^n}{\Delta t}\right)_{xyz}] \quad (6.19)$$

$$B_{xyz} = -[QOWG + \left(\frac{V_p^n C_t^n p^n}{\Delta t}\right)_{xyz}] \quad (6.20)$$

$$QOWG = (B_o - B_g R_{so})_{xyz}^n (GCOT - q_o)_{xyz} +$$

$$(B_w - B_g R_{sw})_{xyz}^n (GCWT - q_w)_{xyz} + B_{g,xyz}^n (GCGT - q_g)_{xyz} \quad (6.21)$$

Phase transmissibilities between blocks x and x-1 or blocks x and x+1 are defined as:

$$A_{\ell,x\pm 1/2} = T_{x\pm 1/2} M_{\ell,x\pm 1/2}, \quad \ell = o, w, g \quad (6.22)$$

The geometrical part of the phase transmissibilities is considered as a harmonic average:

$$T_{x\pm 1/2} = \left(\frac{KA}{\Delta X} \right)_{x\pm 1/2} = \frac{2(KA)_x (KA)_{x\pm 1}}{(\Delta X)_x (KA)_{x\pm 1} + (\Delta X)_{x\pm 1} (KA)_x} \quad (6.23)$$

where, K is absolute permeability; A is cross-sectional area, ΔX is grid block size in the X-direction. The mobility part of the phase transmissibilities is given:

$$M_{\ell,x\pm 1/2} = \left(\frac{K_{r\ell}}{\mu_{\ell} B_{\ell}} \right)_{x\pm 1/2} = \left(\frac{K_{r\ell}}{\mu_{\ell} B_{\ell}} \right)_{\text{upstream}} \quad (6.24)$$

Both the pressure and saturation dependent functions in the mobility term are evaluated using one-point upstream weighting. For example, the relative permeability of phase ℓ at the boundary between block (x,y,z) and block (x+1,y,z) is defined by:

$$K_{r\ell,x+1/2} = K_{r\ell,x} \quad \text{if flow is from x to x+1} \quad (6.25)$$

$$K_{r\ell,x+1/2} = K_{r\ell,x+1} \quad \text{if flow is from x+1 to x} \quad (6.26)$$

Phase transmissibilities in the Y- and Z-directions can be defined similarly using the above notations.

Once the new time level pressures are determined implicitly from equations (6.9) and (6.10), the oil, water, and gas saturations can be explicitly found by discretizing equations (5.73) to (5.75) in both spatial and temporal variables:

$$S_{o,xyz}^{n+1} = \left(\frac{B_o}{V_p}\right)_{xyz}^{n+1} \left[\left(V_p \frac{S_o}{B_o}\right)^n + \Delta t (\Delta A_o \Delta p^{n+1} + GCOT - q_o) \right]_{xyz} \quad (6.27)$$

$$S_{w,xyz}^{n+1} = \left(\frac{B_w}{V_p}\right)_{xyz}^{n+1} \left[\left(V_p \frac{S_w}{B_w}\right)^n + \Delta t (\Delta A_w \Delta p^{n+1} + GCOT - q_w) \right]_{xyz} \quad (6.28)$$

$$S_{g,xyz}^{n+1} = 1 - S_{o,xyz}^{n+1} - S_{w,xyz}^{n+1} \quad (6.29)$$

6.3 Component Equation Approximation

For components such as metabolic products and substrates, the mass transport equations can be written as:

$$\frac{\partial}{\partial t} \left(\frac{\phi S_w}{B_w} C_k + \phi C_{ks} \right) = -\nabla \cdot \left(\bar{u}_w C_k \right) + \nabla \cdot \left(\frac{\phi S_w}{B_w} \bar{D}_{kw} \nabla C_k \right) - \frac{q_w}{V_b} C_k + \frac{\phi S_w}{B_w} R_k \quad (6.30)$$

Since adsorption concentrations for products and substrates are described by Langmuir isotherms, adsorption rates can be expressed as:

$$\frac{\partial C_{ks}}{\partial t} = \frac{a_k}{(1 + b_k C_k)^2} \frac{\partial C_k}{\partial t} \quad (6.31)$$

where, a_k and b_k are Langmuir adsorption constants.

Assuming that changes in porosity (ϕ), phase saturation (S_L), and fluid formation volume factor (B_L) with time are smaller than changes in component concentrations (C_k) with time, the transport equation for component k can be rewritten as:

$$\frac{\partial C_k}{\partial t} = \frac{1}{D_s} \left[-\nabla \left(\frac{\bar{u}_w}{B_w} C_k \right) + \nabla \left(\frac{\phi S_w}{B_w} \bar{D}_{kw} \nabla C_k \right) - \frac{q_w}{V_b} C_k + \frac{\phi S_w}{B_w} R_k \right] \quad (6.32)$$

where

$$D_s = \frac{\phi S_w}{B_w} + \frac{\phi a_k}{(1 + b_k C_k)^2} \quad (6.33)$$

The component transport equation is discretized in the spatial variables while the temporal solution is kept continuous. At grid block (x, y, z), Eq (6.32) is expressed as:

$$\left(\frac{\partial C_k}{\partial t} \right)_{xyz} = \left\{ \frac{1}{D_s} \left[-\nabla \left(\frac{\bar{u}_w}{B_w} C_k \right) + \nabla \left(\frac{\phi S_w}{B_w} \bar{D}_{kw} \nabla C_k \right) - \frac{q_w}{V_b} C_k + \frac{\phi S_w}{B_w} R_k \right] \right\}_{xyz} \quad (6.34)$$

The convection term in Eq (6.34) can be expanded as:

$$\left[\nabla \left(\frac{\bar{u}_w}{B_w} C_k \right) \right]_{xyz} = \left[\frac{\partial}{\partial x} \left(\frac{u_{wx}}{B_w} C_k \right) + \frac{\partial}{\partial y} \left(\frac{u_{wy}}{B_w} C_k \right) + \frac{\partial}{\partial z} \left(\frac{u_{wz}}{B_w} C_k \right) \right]_{xyz} \quad (6.35)$$

The convection term in the X-direction is replaced by the finite difference equation:

$$\left[\frac{\partial}{\partial X} \left(\frac{u_{wx}}{B_w} C_k \right) \right]_{xyz} = \frac{1}{\Delta X_x} \left[\left(\frac{u_{wx}}{B_w} \right)_{x+1/2} C_{k,x+1/2} - \left(\frac{u_{wx}}{B_w} \right)_{x-1/2} C_{k,x-1/2} \right] \quad (6.36)$$

Leonard's third-order upstream formula with a modification for variable grid sizes is employed to approximate the concentrations for component k in Eq.(6.36):^{30,33}

for $\Phi_{w,x-1} > \Phi_{w,x}$

$$C_{k,x-1/2} = C_{k,x-1} + A_{x-1} (C_{k,x-1} - C_{k,x-2}) + 2B_{x-1} (C_{k,x} - C_{k,x-1}) \quad (6.37)$$

for $\Phi_{w,x} > \Phi_{w,x+1}$

$$C_{k,x+1/2} = C_{k,x} + A_x (C_{k,x} - C_{k,x-1}) + 2B_x (C_{k,x+1} - C_{k,x}) \quad (6.38)$$

for $\Phi_{w,x-1} < \Phi_{w,x}$

$$C_{k,x-1/2} = C_{k,x} + 2A_x (C_{k,x-1} - C_{k,x}) + B_x (C_{k,x} - C_{k,x+1}) \quad (6.39)$$

for $\Phi_{w,x} < \Phi_{w,x+1}$

$$C_{k,x+1/2} = C_{k,x+1} + 2A_{x+1} (C_{k,x} - C_{k,x+1}) + B_{x+1} (C_{k,x+1} - C_{k,x+2}) \quad (6.40)$$

where, $\Phi_{w,x}$ is water phase potential in x-direction; and A_x and B_x are defined as

$$A_x = \frac{\Delta X_x}{3(\Delta X_x + \Delta X_{x-1})}, \quad B_x = \frac{\Delta X_x}{3(\Delta X_{x+1} + \Delta X_x)} \quad (6.41)$$

Convection terms in the Y- and Z-directions can be similarly approximated. In implementing the high-order method, an one-point upstream formula is employed whenever a grid block is located outside the reservoir boundary.

Since a full tensor is used to describe the physical dispersion in component transport processes, the dispersion term in Eq (4.34) can be expanded as:

$$\begin{aligned}
& [\nabla(\frac{\phi S_w}{B_w} \bar{D}_{kw} \nabla C_k)]_{xyz} = \\
& \frac{\partial}{\partial X} [\frac{\phi S_w}{B_w} (D_{kw,xx} \frac{\partial C_k}{\partial X} + D_{kw,xy} \frac{\partial C_k}{\partial Y} + D_{kw,xz} \frac{\partial C_k}{\partial Z})]_{xyz} + \\
& \frac{\partial}{\partial Y} [\frac{\phi S_w}{B_w} (D_{kw,yx} \frac{\partial C_k}{\partial X} + D_{kw,yy} \frac{\partial C_k}{\partial Y} + D_{kw,yz} \frac{\partial C_k}{\partial Z})]_{xyz} + \\
& \frac{\partial}{\partial Z} [\frac{\phi S_w}{B_w} (D_{kw,zx} \frac{\partial C_k}{\partial X} + D_{kw,zy} \frac{\partial C_k}{\partial Y} + D_{kw,zz} \frac{\partial C_k}{\partial Z})]_{xyz} \tag{6.42}
\end{aligned}$$

Replacing the spatial derivatives with central finite differences, the dispersion term with differencing carried out in the X-direction can be approximated as:³¹

$$\begin{aligned}
& \frac{\partial}{\partial X} [\frac{\phi S_w}{B_w} (D_{kw,xx} \frac{\partial C_k}{\partial X} + D_{kw,xy} \frac{\partial C_k}{\partial Y} + D_{kw,xz} \frac{\partial C_k}{\partial Z})]_{xyz} = \frac{1}{\Delta X_x} \{ \\
& [(\frac{\phi S_w D_{kw,xx}}{B_w})_{x+1/2} \frac{C_{k,x+1} - C_{k,x}}{\Delta X_{x+1/2}} - (\frac{\phi S_w D_{kw,xx}}{B_w})_{x-1/2} \frac{C_{k,x} - C_{k,x-1}}{\Delta X_{x-1/2}}] +
\end{aligned}$$

$$\left[\left(\frac{\phi S_w D_{kw,xy}}{B_w} \right)_{x+1/2} \frac{(C_{k,y+1} - C_{k,y-1})_{x+1/2}}{\Delta Y_{y+1/2} + \Delta Y_{y-1/2}} - \left(\frac{\phi S_w D_{kw,xy}}{B_w} \right)_{x-1/2} \frac{(C_{k,y+1} - C_{k,y-1})_{x-1/2}}{\Delta Y_{y+1/2} + \Delta Y_{y-1/2}} \right] +$$

$$\left[\left(\frac{\phi S_w D_{kw,xz}}{B_w} \right)_{x+1/2} \frac{(C_{k,z+1} - C_{k,z-1})_{x+1/2}}{\Delta Z_{z+1/2} + \Delta Z_{z-1/2}} - \left(\frac{\phi S_w D_{kw,xz}}{B_w} \right)_{x-1/2} \frac{(C_{k,z+1} - C_{k,z-1})_{x-1/2}}{\Delta Z_{z+1/2} + \Delta Z_{z-1/2}} \right] \quad (6.43)$$

where

$$\Delta X_{x\pm 1/2} = \frac{\Delta X_x + \Delta X_{x\pm 1}}{2} \quad (6.44)$$

$$\Delta Y_{y\pm 1/2} = \frac{\Delta Y_y + \Delta Y_{y\pm 1}}{2} \quad (6.45)$$

$$\Delta Z_{z\pm 1/2} = \frac{\Delta Z_z + \Delta Z_{z\pm 1}}{2} \quad (6.46)$$

The dispersion terms with differencing in the Y- and Z-directions are replaced by similar finite difference formulae.

A first-order upstream formula is used to approximate the concentrations with subscript of $x\pm 1/2$ in Eq (6.43):³¹

$$(C_{k,y\pm 1})_{x\pm 1/2} = (C_{k,y\pm 1})_{x\pm 1} \quad \text{for } (\Phi_w)_{x\pm 1} > (\Phi_w)_x \quad (6.47)$$

$$(C_{k,z\pm 1})_{x\pm 1/2} = (C_{k,z\pm 1})_{x\pm 1} \quad \text{for } (\Phi_w)_{x\pm 1} > (\Phi_w)_x \quad (6.48)$$

$$(C_{k,y\pm 1})_{x\pm 1/2} = (C_{k,y\pm 1})_x \quad \text{for } (\Phi_w)_{x\pm 1} < (\Phi_w)_x \quad (6.49)$$

$$(C_{k,z\pm 1})_{x\pm 1/2} = (C_{k,z\pm 1})_x \quad \text{for } (\Phi_w)_{x\pm 1} < (\Phi_w)_x \quad (6.50)$$

Similar treatments can be made for the concentrations with subscripts of $y\pm 1/2$ and $z\pm 1/2$ in dispersion terms with differencing in the Y- and Z-directions.

The coefficient products of the physical dispersion terms in Eq (6.43) are computed from the following discrete formulae:

$$\left(\frac{\phi S_w D_{kw,xx}}{B_w}\right)_{x\pm 1/2} = \frac{D_k}{\tau} \left(\frac{\phi S_w}{B_w}\right)_{x\pm 1/2} + \frac{(\alpha_{lw} - \alpha_{tw}) (u_{wz}^2)_{x\pm 1/2}}{B_{w,x\pm 1/2} |\bar{u}_w|_{x\pm 1/2}} + \frac{\alpha_{tw} |\bar{u}_w|_{x\pm 1/2}}{B_{w,x\pm 1/2}} \quad (6.51)$$

$$\left(\frac{\phi S_w D_{kw,xy}}{B_w}\right)_{x\pm 1/2} = \frac{(\alpha_{lw} - \alpha_{tw})}{B_{w,x\pm 1/2} |\bar{u}_w|_{x\pm 1/2}} |u_{wx} u_{wy}|_{x\pm 1/2} \quad (6.52)$$

$$\left(\frac{\phi S_w D_{kw,xz}}{B_w}\right)_{x\pm 1/2} = \frac{(\alpha_{lw} - \alpha_{tw})}{B_{w,x\pm 1/2} |\bar{u}_w|_{x\pm 1/2}} |u_{wx} u_{wz}|_{x\pm 1/2} \quad (6.53)$$

where

$$|\bar{u}_w|_{x\pm 1/2} = \sqrt{(u_{wx})_{x\pm 1/2}^2 + (u_{wy})_{x\pm 1/2}^2 + (u_{wz})_{x\pm 1/2}^2} \quad (6.54)$$

Darcy velocities such as $(u_{wy})_{x\pm 1/2}$ and $(u_{wz})_{x\pm 1/2}$ in Eqs. (6.52) to (6.54) are replaced by the average, first-order upstream velocities:³¹

for $(\Phi_w)_x > (\Phi_w)_{x\pm 1}$

$$(u_{wy})_{x\pm 1/2,y,z} = (u_{wy})_{x,y,z} = \frac{1}{2}[(u_{wy})_{x,y+1/2,z} + (u_{wy})_{x,y-1/2,z}] \quad (6.55)$$

$$(u_{wz})_{x\pm 1/2,y,z} = (u_{wz})_{x,y,z} = \frac{1}{2}[(u_{wz})_{x,y,z+1/2} + (u_{wz})_{x,y,z-1/2}] \quad (6.56)$$

for $(\Phi_w)_x < (\Phi_w)_{x\pm 1}$

$$(u_{wy})_{x\pm 1/2,y,z} = (u_{wy})_{x\pm 1,y,z} = \frac{1}{2}[(u_{wy})_{x\pm 1,y+1/2,z} + (u_{wy})_{x\pm 1,y-1/2,z}] \quad (6.57)$$

$$(u_{wz})_{x\pm 1/2,y,z} = (u_{wz})_{x\pm 1,y,z} = \frac{1}{2}[(u_{wz})_{x\pm 1,y,z+1/2} + (u_{wz})_{x\pm 1,y,z-1/2}] \quad (6.58)$$

For velocities such as $(u_{wx})_{y\pm 1/2}$, $(u_{wz})_{y\pm 1/2}$, $(u_{wx})_{z\pm 1/2}$, and $(u_{wy})_{z\pm 1/2}$ in the dispersion terms with differencing in the Y- and Z-directions, similar procedures can be employed for the approximations.

The transport equation for bacteria in aqueous suspension is written as:

$$\frac{\partial}{\partial t} \left(\frac{\phi S_w}{B_w} C_1 + \phi C_{1s} \right) = -\nabla \left(\frac{\bar{u}_w}{B_w} C_1 \right) - K_c \nabla (C_1 \nabla \ln C_8) + \nabla \left(\frac{\phi S_w}{B_w} \bar{D}_{1w} \nabla C_1 \right) - \frac{q_w}{V_b} C_1 + \frac{\phi S_w}{B_w} R_1 \quad (6.59)$$

where, C_1 is the concentration of the flowing bacteria and C_8 is the concentration of the carbon-source nutrient. Adsorption of cells on pore surfaces is considered as a dynamic adsorption process. The adsorption rate is expressed as:

$$\frac{\partial C_{1s}}{\partial t} = R_r - R_d \quad (6.60)$$

where, R_r and R_d are rates of bacterial retention and detachment. For simplicity, the bacterial transport equation (6.59) is rewritten as:

$$\begin{aligned} \frac{\partial C_1}{\partial t} = \frac{1}{D_s} & \left[-\nabla \left(\frac{\bar{u}_w}{B_w} C_1 \right) - K_c \nabla (C_1 \nabla \ln C_8) + \nabla \left(\frac{\phi S_w}{B_w} \bar{D}_{1w} \nabla C_1 \right) \right. \\ & \left. - \frac{q_w}{V_b} C_1 + \frac{\phi S_w}{B_w} R_1 + \phi (R_d - R_r) \right] \end{aligned} \quad (6.61)$$

where

$$D_s = \frac{\phi S_w}{B_w} \quad (6.62)$$

Discretization of the bacterial transport equation (6.61) in the spatial variable is essentially the same as that of equation (6.34) for product and substrate, except that the chemotaxis term in equation (6.61) needs to be treated with special care. The chemotaxis term can be further expanded as:

$$\begin{aligned}
K_c \nabla(C_1 \nabla \ln C_8) &= K_c \left[\frac{\partial}{\partial X} \left(C_1 \frac{\partial \ln C_8}{\partial X} \right) + \frac{\partial}{\partial Y} \left(C_1 \frac{\partial \ln C_8}{\partial Y} \right) + \frac{\partial}{\partial Z} \left(C_1 \frac{\partial \ln C_8}{\partial Z} \right) \right] \\
&= K_c \left[\frac{\partial}{\partial X} \left(\frac{1}{C_8} \frac{\partial C_8}{\partial X} C_1 \right) + \frac{\partial}{\partial Y} \left(\frac{1}{C_8} \frac{\partial C_8}{\partial Y} C_1 \right) + \frac{\partial}{\partial Z} \left(\frac{1}{C_8} \frac{\partial C_8}{\partial Z} C_1 \right) \right] \quad (6.63)
\end{aligned}$$

The X-direction component of the chemotaxis term is approximated as:

$$\left[\frac{\partial}{\partial X} \left(\frac{1}{C_8} \frac{\partial C_8}{\partial X} C_1 \right) \right]_{xyz} = \frac{1}{\Delta X_x} \left[\left(\frac{1}{C_8} \frac{\partial C_8}{\partial X} C_1 \right)_{x+1/2} - \left(\frac{1}{C_8} \frac{\partial C_8}{\partial X} C_1 \right)_{x-1/2} \right] \quad (6.64)$$

where,

$$\left(\frac{1}{C_8} \frac{\partial C_8}{\partial X} \right)_{x\pm 1/2} = \frac{C_{8,x\pm 1} - C_{8,x}}{(C_8 \Delta X)_{x\pm 1/2}} = \frac{4(C_{8,x\pm 1} - C_{8,x})}{(C_{8,x} + C_{8,x\pm 1})(\Delta X_x + \Delta X_{x\pm 1})} \quad (6.65)$$

Again, Leonard's third-order upstream formula with a modification for variable grid sizes is used to approximate the bacterial concentrations in Eq. (6.64):

for $C_{8,x-1} > C_{8,x}$

$$C_{1,x-1/2} = C_{1,x-1} + A_{x-1}(C_{1,x-1} - C_{1,x-2}) + 2B_{x-1}(C_{1,x} - C_{1,x-1}) \quad (6.66)$$

for $C_{8,x} > C_{8,x+1}$

$$C_{1,x+1/2} = C_{1,x} + A_x(C_{1,x} - C_{1,x-1}) + 2B_x(C_{1,x+1} - C_{1,x}) \quad (6.67)$$

for $C_{8,x-1} < C_{8,x}$

$$C_{1,x-1/2} = C_{1,x} + 2A_x(C_{1,x-1} - C_{1,x}) + B_x(C_{1,x} - C_{1,x+1}) \quad (6.68)$$

for $C_{8,x} < C_{8,x+1}$

$$C_{1,x+1/2} = C_{1,x+1} + 2A_{x+1}(C_{1,x} - C_{1,x+1}) + B_{x+1}(C_{1,x+1} - C_{1,x+2}) \quad (6.69)$$

6.4 Well Model

In this section, well inflow performance is discussed. Wells, either producers or injectors, are treated as source/sink terms in the numerical simulator. Basically, constraints of either constant flow rate or constant flowing bottomhole pressure can be imposed on wells. From Darcy's law, the well volumetric flow rate for phase ℓ is proportional to the pressure difference between the gridblock pressure and flowing bottomhole pressure:

$$q_\ell = PI_\ell(p - p_{wf}) \quad (6.70)$$

where, p is the gridblock pressure; p_{wf} is the flowing bottomhole pressure; PI_ℓ is productivity index for phase ℓ , which is defined as:

$$PI_\ell = T_w \frac{\lambda_\ell}{B_\ell} \quad (6.71)$$

where, λ_ℓ and B_ℓ are mobility and formation volume factor for phase ℓ ; T_w is defined as well transmissivity to connect flow between wellbore and gridblock:

$$T_w = \frac{\Delta Z \sqrt{K_x K_y}}{\ln\left(\frac{r_o}{r_w}\right) + S} \quad (6.72)$$

where, K_x and K_y are permeabilities in the X- and Y-directions; ΔZ is gridblock size in the Z-direction; r_w is wellbore radius; S is skin factor; The pressure equivalent radius of the gridblock (r_o) is computed using Peaceman's formula:³⁴

$$r_o = \frac{\left[\left(\frac{K_y}{K_x}\right)^{1/2} \Delta X^2 + \left(\frac{K_x}{K_y}\right)^{1/2} \Delta Y^2\right]^{1/2}}{\left(\frac{K_y}{K_x}\right)^{1/4} + \left(\frac{K_x}{K_y}\right)^{1/4}} \quad (6.73)$$

Next, well constraints such as flow rates and flowing bottomhole pressures will be discussed.

6.4.1 Constant Oil Production Rate

If the oil production rate is specified as q_o for a well, the oil, water, and gas production rates from layer z in this well can be computed by:

$$q_{o,z} = q_o \frac{(PI_L)_z}{\sum_{z=1}^{nz} (PI_L)_z} \quad (6.74)$$

$$q_{w,z} = q_{o,z} \left(\frac{\lambda_w / B_w}{\lambda_o / B_o} \right)_z \quad (6.75)$$

$$q_{g,z} = q_{o,z} \left(\frac{\lambda_g / B_g}{\lambda_o / B_o} \right)_z + q_{o,z} R_{so,z} + q_{w,z} R_{sw,z} \quad (6.76)$$

where, nz is total number of completion intervals.

6.4.2 Constant Total Liquid Production Rate

Total oil and water mobility ratios are expressed as:

$$\alpha_{ot} = \sum_{z=1}^{nz} \left(\frac{\lambda_o / B_o}{\lambda_o / B_o + \lambda_w / B_w} \right)_z \quad (6.77)$$

$$\alpha_{wt} = \sum_{z=1}^{nz} \left(\frac{\lambda_w / B_w}{\lambda_o / B_o + \lambda_w / B_w} \right)_z \quad (6.78)$$

If the total liquid production rate at surface condition is assumed to be q_t , total oil rate is calculated by:

$$q_o = \left(\frac{\alpha_{ot}}{\alpha_{ot} + \alpha_{ot}} \right) q_t \quad (6.79)$$

If the total oil production rate is known, the oil, water, and gas rates for each layer can be calculated using Eqs (6.74) through (6.76).

6.4.3 Constant Water or Gas Injection Rates

Total water or gas injection rates are specified as q_w or q_g . The water or gas injection rates for each layer are computed based on total mobilities instead of only injected fluid mobility:

$$q_{w,z} = q_w \frac{[T_w(\lambda_o + \lambda_w + \lambda_g)]_z}{\sum_{z=1}^{nz} [T_w(\lambda_o + \lambda_w + \lambda_g)]_z} \quad (6.80)$$

$$q_{g,z} = q_g \frac{[T_w(\lambda_o + \lambda_w + \lambda_g)]_z}{\sum_{z=1}^{nz} [T_w(\lambda_o + \lambda_w + \lambda_g)]_z} \quad (6.81)$$

6.4.4 Constant Bottom-Hole Pressure for Producer

In this simulator it is assumed that the flowing bottom-hole pressure (BHP) at the top layer is specified for the producer. The flowing BHP at lower layers are computed by:

$$p_{wf,z} = p_{wf,z-1} + 0.5(\bar{\gamma}_z \Delta Z_z + \bar{\gamma}_{z-1} \Delta Z_{z-1}) \quad (6.82)$$

where, the average specific weight of wellbore fluids is defined as:

$$\bar{\gamma}_z = \frac{\sum_{\ell=o,w,g} (\gamma_\ell PI_\ell)_z}{\sum_{\ell=o,w,g} (PI_\ell)_z} \quad (6.83)$$

6.4.5 Constant Bottom-Hole Pressure for Injector

Similarly, the bottom-hole pressure at the top layer can be specified for an injection. The injection BHP for the lower layers are calculated as follows:

$$p_{wf,z} = p_{wf,z-1} + 0.5(\gamma_{inj,z} \Delta Z_z + \gamma_{inj,z-1} \Delta Z_{z-1}) \quad (6.84)$$

where, $\gamma_{inj,z}$ is specific weight for the injected fluid at layer z.

6.4.6 Implicit Pressure Constraints

For constant bottom-hole pressure wells, production or injection rates for phase ℓ at layer z can be expressed as:

$$q_{\ell,z} = (PI_\ell)_z (p^{n+1} - p_{wf})_z \quad (6.85)$$

The above equation is substituted into the pressure equation (6.3) so that pressures can be solved implicitly. The calculated block pressure p^{n+1} is then used to determine the

phase flow rate $q_{\ell,z}$. This implicit pressure procedure requires that the original coefficients (E_{xyz} and B_{xyz}) of the pressure equation be redefined as:

$$E_{xyz}^{new} = E_{xyz}^{old} - \beta_{t,xyz} \quad (6.86)$$

$$B_{xyz}^{new} = B_{xyz}^{old} - \beta_{t,xyz} P_{wf,xyz} \quad (6.87)$$

$$\hat{B}_{xyz}^{new} = \hat{B}_{xyz}^{old} - \beta_{t,xyz} (p_{wf,xyz} - p_{xyz}^n) \quad \text{for the perturbation method} \quad (6.88)$$

where

$$\beta_{t,xyz} = [(B_o - B_g R_{so})PI_o + (B_w - B_g R_{sw})PI_w + B_g PI_g]_{xyz} \quad (6.89)$$

6.5 Time Step Selection

An automatic time step selector is incorporated in the simulator to avoid numerical instability and to save computational time.

First, the relative changes in primary dependent variables (pressures, saturations, and concentrations) over a time step are calculated for each grid block:

$$(\Delta p)_m = \frac{|p_m^{n+1} - p_m^n|}{p_m^{n+1}} \quad (6.90)$$

$$(\Delta S_\ell)_m = \frac{|(S_\ell)_m^{n+1} - (S_\ell)_m^n|}{(S_\ell)_m^{n+1}} \quad (6.91)$$

$$(\Delta C_k)_m = \frac{|(C_k)_m^{n+1} - (C_k)_m^n|}{(C_k)_m^{n+1}} \quad (6.92)$$

where, m , ℓ , and k are numbers for grid blocks, phases, and components, respectively.

Next, maximum relative changes are determined for each variable:

$$(\Delta p)_{\max} = \max_m [(\Delta p)_m] \quad (6.93)$$

$$(\Delta S)_{\max} = \max_\ell \{ \max_m [(\Delta S_\ell)_m] \} \quad (6.94)$$

$$(\Delta C)_{\max} = \max_k \{ \max_m [(\Delta C_k)_m] \} \quad (6.95)$$

Finally, to check upper-limit violation, the following criteria are established:

$$(\Delta p)_{\max} \leq (\Delta p)_{\lim} \quad (\Delta S)_{\max} \leq (\Delta S)_{\lim} \quad (\Delta C)_{\max} \leq (\Delta C)_{\lim} \quad (6.96)$$

where, $(\Delta p)_{\lim}$, $(\Delta S)_{\lim}$, and $(\Delta C)_{\lim}$ are upper limits specified for relative changes in pressures, saturations, and concentrations, respectively.

If all the criteria in Eq.(6.96) are satisfied, time step can be increased by multiplying the factor F_{inc} , otherwise, the time step is reduced by the factor F_{dec} :

$$\Delta t^{n+1} = F_{inc} \Delta t^n \quad (6.97)$$

$$\Delta t^{n+1} = F_{\text{dec}} \Delta t^n \quad (6.98)$$

However, the new time step should be limited by:

$$\Delta t_{\text{min}} \leq \Delta t^{n+1} \leq \Delta t_{\text{max}} \quad (6.99)$$

where, Δt_{min} and Δt_{max} are specified lower and upper limits for time step size.

6.6 Vectorization

All variables are vectorized so that the variables are stored in one-dimensional arrays following the order of grid-block numbering. This offers advantage and flexibility in computation.

In one form of natural ordering, gridblocks are numbered so that:

for $z = 1, 2, \dots, N_z$

$$y = 1, \quad x = 1, 2, \dots, N_x \quad (6.100)$$

$$y = 2, \quad x = 1, 2, \dots, N_x \quad (6.101)$$

.....

$$y = N_y, \quad x = 1, 2, \dots, N_x \quad (6.102)$$

where, N_x , N_y , N_z are total block numbers in the X-, Y-, and Z-directions. Thus, a relationship between block ordering number $\{n_b\}$ and block coordinate $\{x, y, z\}$ can be established:

$$n_b = x + (y-1)N_x + (z-1)N_xN_y, \quad n_b = 1, 2, 3, \dots, N \quad (6.103)$$

where, N is total block number for the grid system:

$$N = N_xN_yN_z \quad (6.104)$$

Therefore, the following equivalent relationships hold:

$$\{x \pm 1\} \Leftrightarrow \{n_b \pm 1\} \quad (6.105)$$

$$\{y \pm 1\} \Leftrightarrow \{n_b \pm N_x\} \quad (6.106)$$

$$\{z \pm 1\} \Leftrightarrow \{n_b \pm N_xN_y\} \quad (6.107)$$

$$\{x \pm 2\} \Leftrightarrow \{n_b \pm 2\} \quad (6.108)$$

$$\{y \pm 2\} \Leftrightarrow \{n_b \pm 2N_x\} \quad (6.109)$$

$$\{z \pm 2\} \Leftrightarrow \{n_b \pm 2N_xN_y\} \quad (6.110)$$

$$\{x \pm 1, y \pm 1\} \Leftrightarrow \{n_b \pm 1 \pm N_x\} \quad (6.111)$$

$$\{x \pm 1, z \pm 1\} \Leftrightarrow \{n_b \pm 1 \pm N_x N_y\} \quad (6,112)$$

$$\{y \pm 1, z \pm 1\} \Leftrightarrow \{n_b \pm N_x \pm N_x N_y\} \quad (6,113)$$

$$\{x \pm n_x, y \pm n_y, z \pm n_z\} \Leftrightarrow \{n_b \pm n_x \pm n_y N_x \pm n_z N_x N_y\} \quad (6,114)$$

where

$$1 \leq n_x \leq N_x, \quad 1 \leq n_y \leq N_y, \quad 1 \leq n_z \leq N_z \quad (6,115)$$

6.7 Computational Procedure

The numerical solutions for mathematical models involves several steps. First the pressure distributions are solved implicitly. Second the phase saturations are calculated explicitly. Third the Darcy fluxes for the aqueous phase are computed. Finally, this is followed by the explicit solution of the convection-dispersion equations for components.

The pressure equation is solved using LSOR algorithm.^{35,36} Solutions for the component equations are obtained using method of lines (MOL)³⁷ and the fourth-order Runge-Kutta-Fehlberg (RKF) formula.³⁸

Finite difference formulae for the black oil model and component transport equations are summarized in Tables 6.1 and 6.2.

7. SIMULATOR VALIDATION AND APPLICATIONS

The mathematical formulation of MEOR processes developed in Chapter 5, and the numerical techniques used to solve the MEOR model, described in Chapter 6 were verified using analytical solutions and other simulators. Special cases regarding growth inhibition, chemotaxis, microbial plugging, biopolymer, biosurfactant, biogases were used to test the simulator and investigate the mechanisms involved in MEOR processes. The validation and case studies were necessary to ensure the correctness of the proposed models and program coding. Finally, the simulator was used to model MEOR experiments conducted in the laboratory.

7.1 Verification with Analytical Solutions

In this section, the numerical results were compared with analytical solutions for a one-dimensional immiscible displacement, a one-dimensional convection and dispersion, and a two-dimensional ideal tracer flow.

7.1.1 One-Dimensional Waterflood

By neglecting capillary pressure and gravity effects, an analytical solution is available for the linear incompressible, immiscible waterflood case known as the Buckley-Leverett problem.³⁹ Table 7.1 contains the input data necessary for an one-dimensional numerical solution. The 100-, 50-, and 25-block grid systems were used to test the model. Figure 7.1 shows the water saturation profiles after 40 days of water injection. Numerical solutions for various grid systems were stable. The finer grid system gave better

agreement between simulation results and the analytical solution except at the displacing front where small numerical smearing occurred.

7.1.2. Linear Convection-Dispersion Equation

This sample problem was designed to test the Leonard's third-order upwinding formula³³ incorporated in the MEOR simulator. Compared with the first- and second-order convective differencing formulae, the third-order scheme gave less oscillation and more accurate results.⁴⁰ A one-dimensional miscible flow was simulated. The injected fluid was identical to the resident fluid in properties. The simulation was run at a Peclet number of 500 and with grid systems containing 100, 50, and 25 blocks. The input data are given in Table 7.2. The computed concentration profile at 0.5 pore volume injected is compared with the analytical solution of the one-dimensional convection-dispersion equation, as shown in Figure 7.2. No oscillation was observed for any of the numerical results. Coarser grid systems gave solutions with more numerical dispersion. An excellent match between simulation results and analytical solution was achieved with the 100-block grid system.

7.1.3 Ideal Tracer Flow in Five-Spot Pattern

The tracer breakthrough curve (displacing fluid cut versus pore volume injected) for different Peclet numbers and flow patterns has been obtained by application of mixing theory.⁴¹ The analytical solution for an ideal tracer flow with a unit mobility ratio in a homogeneous five-spot pattern was selected for solution comparison. A $20 \times 20 \times 1$ grid system was employed to model the flow of a 2% pore volume tracer slug with a longitudinal dispersivity of 0.2 ft in one-quarter of five-spot pattern with sides of 100 ft

(Table.7.3). Figure 7.3 shows a comparison of simulation results and analytical solution. The calculated results obtained from the MEOR simulator were close to analytical solution. The observed discrepancy could be explained to be due to numerical dispersion since there were only 28 blocks along diagonal direction for the $20 \times 20 \times 1$ grid system. The numerical solution could be improved if a finer grid pattern was used.

7.2 Comparison with ECLIPSE Simulator

A two-dimensional waterflood case was chosen to test the MEOR simulator by comparison with the ECLIPSE simulator, a commercial three-phase, three-dimensional black oil model.

7.2.1 Waterflood in Five-Spot Pattern

The immiscible displacement of oil by water in a homogeneous one-quarter of a five-spot well pattern was selected to verify the black oil model portion of the MEOR simulator. Input data are listed in Table 7.4. A grid system of $10 \times 10 \times 1$ was used. Figures 7.4 to 7.9 show comparisons of the MEOR simulator with the ECLIPSE simulator for oil production rate, water cut, water saturation at a specified block (5,5,1), average reservoir pressure, and bottom-hole pressures (BHP) for the injector and producer. In general, agreement between the two simulators was good. However, the MEOR simulator predicted a little lower injection BHP and higher production BHP than those did the ECLIPSE simulator. This might be due to slightly different well models incorporated into the two simulators.

7.3 Case Studies for MEOR Processes

Mechanisms involved in MEOR techniques were investigated through simulation of processes regarding growth inhibition, chemotaxis, microbial plugging, mobility control by biopolymers, interfacial tension reduction by biosurfactants, and biogas effects. The following hypothetical cases were designed for numerical simulation.

7.3.1 Growth Inhibition by End Products

Bacterial growth can be inhibited by metabolic products such as alcohol. This may become important when the concentrations of inhibitors increase significantly at the later stages of growth and metabolism. A case of cell growth inhibition by alcohol in liquid cultures was selected for simulation. Necessary input data are given in Table 7.5. When terms were included to account for the inhibition of growth by metabolic end products, the duration of the exponential phase of growth was shorter and less biomass was produced compared to the case where no inhibition of growth by metabolic end products occurs (Figure 7.10).

7.3.2 Chemotactic Migration of Cells

Mechanisms by which bacteria can penetrate porous material under static conditions include growth, mobility, chemotaxis, or a combination of these modes of locomotion. The movement of microorganisms by self-propulsion in subsurface formation could be an important issue for environmental problems. Experimental results⁴² show that chemotactic strains move through the core in a bank-like fashion while migration of

nonchemotactic strains appears dispersive. A numerical study was conducted to investigate chemotactic movement of motile bacteria under static conditions. Input data are given in Table 7.6. A six-inch core with a diameter of two inches was partitioned lengthwise into 100 grid blocks. Initially, nutrient was distributed uniformly throughout the core and bacterial cells were introduced into the first 10 blocks. This duplicated the actual experimental protocol.⁴² The core was sealed for the duration of the experiment. Figures 7.11 and 7.12 show profiles for biomass and glucose concentrations after 50 hours of growth. In this study, cell mobility was modeled by effective diffusion including Brownian motion and tumbling. Diffusion phenomenon was a random process. Compared to the case where cell migration was due to diffusion, chemotactic migration of bacteria in porous media appeared band-like. The results were expected since microbial chemotaxis is a systematical process where the net movement of cells is towards a higher nutrient concentration.

7.3.3 Microbial Plugging

A two-layer cross section system was chosen to simulate selective plugging of porous media by bacterial cells. Table 7.7 defines the grid system and presents a list of all pertinent data. The top layer of the system is a high-permeability zone and the bottom layer is a low-permeability zone. The MEOR treatment began with the injection of 0.3 pore volumes of biomass and a nutrient solution after waterflood breakthrough. This was followed by incubation and a subsequent waterflood. As shown in Figure 7.13, the permeability decreased by 60% near the wellbore in the top layer, but only about 5% reduction in permeability was observed in the bottom layer. This was expected since the high-permeability zone should receive a larger portion of the injected cells and nutrients

than the low-permeability zone. Selective plugging of the top layer caused a diversion of injected water into the low-permeability zone. Additional oil was recovered as results of improvement in volumetric sweep efficiency. Figures 7.14 and 7.15 give comparisons between the conventional waterflood and waterflood after microbial plugging for oil production rates and oil recovery factors.

7.3.4 Mobility Control by Biopolymer

The sweep efficiency of a displacement process may be improved by mobility control that reduces viscous fingering. This can be done by increasing the viscosity of the displacing fluid with biopolymer. A scenario was designed to test the effects of mobility control by in situ biopolymer production. Injection of 10% pore volumes of biomass and nutrient solution into the core along with the waterflood was followed by an incubation period to allow biopolymer production. This was followed by post MEOR waterflood for oil recovery. The fluid and microbial data are given in Table 7.8. The proposed viscosity model (Eq. 5.86) was used to adjust the viscosity of the biopolymer solution to the level of the oil viscosity. This resulted in a unit viscosity ratio which was favorable for the displacement process. Figure 7.16 shows a post waterflood process after microbial growth occurred in the core. In this process the biopolymer solution slug with the same viscosity as the oil displaced the oil more efficiently than did a conventional waterflood without the biopolymer. This is shown by the fact that the waterflood with the biopolymer solution gave the steep water saturation front while the conventional waterflood had a relatively flat front. Therefore, oil recovery was enhanced through the process of mobility control caused by biopolymer production, as shown in Figures 7.17 and 7.18.

7.3.5 Interfacial Tension Reduction by Biosurfactants

Biosurfactants produced during the growth and metabolism of bacteria may reduce interfacial tension (IFT) between the oil and water phases. This leads to mobilization and solubilization of residual oil trapped in porous media. Additional oil recovery is expected from this process. A linear core system was selected for simulation of this MEOR mechanism (Table 7.9). The core was assumed to have been flooded to residual oil saturation prior to the MEOR treatment. The simulated MEOR treatment involved nutrient and biomass injection, incubation, and post-incubation brine flood. After microbial growth and metabolism occurred in the core, biosurfactant was produced which significantly decreased the interfacial tension between the oleic and brine phases. Figures 7.19 and 7.20 show the changes in oil production rate, interfacial tension, recovery factor, and capillary number during post-incubation brine flood. It is noted that the oil production rate kept relatively constant and the recovery factor increased linearly as the biosurfactant-rich solution displaced the residual oil where interfacial tension was low and capillary number was high. However, once fresh brine breakthrough occurred, oil production dropped dramatically since the IFT between the fresh brine and the residual oil was quite high.

7.3.6 Effects of Biogases

Gases produced during growth and metabolism include carbon dioxide, nitrogen, and hydrogen. These gases may increase reservoir pressure, swell the oil phase, and reduce oil viscosity so that additional oil may be recovered. A simulation study was conducted based on a CO₂-producing bacterium and a linear core system (Table 7.10). As

shown in Figure 7.21, the growth and metabolism of bacteria in a core flooded with a nutrient solution (111 m moles per liter of glucose) resulted in production of 200 m moles per liter of carbon dioxide which caused about a 250 psig increase in the pore pressure. It is interesting that the increase in pore pressure showed a trend similar to an exponential bacterial growth curve (Figure 7.22). However, during post brine flush, 80% of the carbon dioxide was produced and no oil was recovered, as shown in Figure 7.23. Based on the data given in Table 7.10, a solution gas-oil ratio can be estimated as 10 scc/scc (55 scf/stb). At this solution gas-oil ratio, the oil swelling factor is about 1.04. It appears that the amount of gases produced from MEOR processes are not likely sufficient to recover residual oil.

7.4 Simulation of Experiments

In this section the MEOR numerical simulator was used to simulate laboratory experiments. The experiments to be simulated included the movement of chemotactic and nonchemotactic bacterial strains of *E. coli* in static sand-packed cores, and Berea sandstone core-flooding experiments using gas- or surfactant-producing bacteria.

7.4.1 Core Flooding with Indigenous Bacteria

Experiments were conducted to study mechanisms involved in MEOR processes.⁴³ Data from these experiments were used earlier to test the prediction of our one-dimensional model¹³ and were reported in our first annual report.⁴⁹ Indigenous bacterial strains and nutrients (glucose and ammonium nitrate) were injected into Berea sandstone core #6 (6 inches in length and 2 inches in diameter) and the core was then incubated to

allow time for microbial growth and metabolism. After MEOR treatments permeability reduction and residual oil recovery were observed. End products detected in effluents of the core include acetate, carbon dioxide, and nitrogen. Table 7.11 gives the input data used for numerical simulation. Figures 7.24 to 7.28 show comparisons of simulation solutions with the experimental results for effluent acetate concentration, total gas production, glucose consumption, nitrate consumption, and permeability reduction. No significant metabolic products were observed during the first four treatments. This was probably because cell populations were too low to result in detectable production of metabolites during this time. A good match between experimental data and simulation results was achieved for total gases production which included CO₂ and N₂. The predicted consumption of glucose and nitrate was very close to that actually measured in the experiment. The surface retention and pore-throat plugging model (Eq.5.23) gave a good agreement for permeability reduction between experimental data and simulation results.

7.4.2 Chemotactic and Nonchemotactic Strains

The importance of chemotaxis was investigated in the laboratory experiments using strains of *E. coli*.⁴² These data were previously reported in our first annual report.⁴⁹ A 10-cm-long, sand-packed core was used. The core was divided into 5 sections of equal length in order to monitor the bacterial transport along the length of the core. The core was filled with mobility growth medium (MGM).⁴² The motile nonchemotactic strain PR5232 and its parental chemotactic strain, RP437, were each inoculated to the first section of separate cores. The cores were then placed in a horizontal position inside the anaerobic chamber for incubation. The concentrations of these strains were determined along the length of MGM-saturated cores with time.^{42,49} Input data for the numerical

study are listed in Tables 7.12 and 7.13. For simulation, the core was divided lengthwise into 50 grid blocks. Nutrients were distributed uniformly throughout the core and the first 10 blocks were inoculated with bacteria. Figures 7.29 and 7.30 show comparisons between experimental data and simulation results for the concentration profiles of the chemotactic and nonchemotactic strains along the length of the core. The overall matches was good. The chemotactic strain (RP437) grew and moved through cores in a band-like fashion with a high-concentration of cells in the moving front (10^7 cell/ml) which was accurately predicted by the MEOR simulator. The cells of the nonchemotactic strain (RP5323) moved through cores in a more diffusive manner with a low-concentration cells in the moving front (10^3 cell/ml). This was also simulated by the model.

7.4.3 Core Flooding with *Clostridium acetobutylicum*

Clostridium acetobutylicum was used for a MEOR core flooding experiment. This organism produces a mixture of acids, solvents, and gases from glucose. A mineral salts medium with glucose and yeast extract was used.⁴² Core #1, with dimensions of $11\frac{3}{16}$ inches in length and 2 inches in diameter, was cut from a block of Berea sandstone. Petrophysical properties of this core are listed in Table 7.14. The experimental involved bacterial and nutrient injection, incubation under high pressures (500-1000 psig), and brine flush. Metabolic products that were produced included acetate, butyrate, ethanol, butanol, and carbon dioxide. The experimental data are summarized in Table 7.15. For computational convenience, the acid component represents the sum of acetate and butyrate while the alcohol component represents the sum of ethanol and butanol. A 50-block grid system was used for simulating the experiment conducted with core #1. Table 7.16 gives the necessary input data. The results from numerical solution along with the

experimental data are plotted in Figures 7.31 to 7.35. The MEOR simulator predicted lower acid and alcohol production than obtained in the experiment. Good agreement was observed for CO₂ production. Simulation results showed a consumption of about 90% of the glucose during treatments 2 to 5, which was much higher than the experimental glucose consumption. High concentration of the unused glucose in the effluent was probably due to desorption of glucose which was sorbed in the rock during nutrient injection.

7.4.4 Core Flooding with *Bacillus* Strain JF-2

MEOR treatments with *Bacillus* strain JF-2 were conducted in Berea core #4. *Bacillus* strain JF-2 produces a biosurfactant which reduces the interfacial tension between oil and water phases. After the core was saturated with brine, it was flooded to connate water saturation with oil, and then flooded to residual oil saturation with brine. The initial core data are shown in Table 7.17. Experimental processes included injection of bacteria and nutrients, incubation of the core to allow time for microbial growth and metabolism, and a post-incubation flush with brine to recover oil and metabolic end-products. Recovery of 23% of the residual oil after five treatments was observed. The experimental results are summarized in Table 7.18. To simulate this experiment, a 50-block grid was used. The simulation input data are given in Table 7.19. As seen in Figures 7.36 to 7.38, simulation results showed that oil recovery was proportional to biosurfactant production. However, the simulator did not predict any increase in permeability as was observed during early treatments (Figure 7.39). Overall matches was reasonable.

Table 7.1 Input Data for One-Dimensional Waterflood Run

Variables	Values
Reservoir Dimension: NX x NY x NZ	25, 50, 100 x 1 x 1

5	3	19.6	197	64	63	29

a: At Standard Condition;

b: Acid = Acetate + Butyrate;

c: Alcohol = Ethanol + Butanol;

d: Initial Glucose = 1528 mg (20 mg/ml).

Table 7.16 Input Data for Core #1

Variables	Values
System Dimension: NX x NY x NZ	50 x 1 x 1
Grid Block Size: $\Delta X \times \Delta Y \times \Delta Z$	0.5684x 4.502 x 4.502 cm
Absolute Permeabilities	$K_x = K_y = K_z = 178$ md
Porosity	18.4 %
Oil and Water Relative Permeabilities	Corey's Model ⁴⁵
Endpoints of Phase Relative Permeabilities	$K_{ro}^0 = 0.63$; $K_{rw}^0 = 0.24$; $K_{rg}^0 = 0.1$
Exponents of Phase Relative Permeabilities	$e_o = 2.5$; $e_w = 2.1$; $e_g = 2.1$
Residual Phase Saturations	$S_{or} = 29$; $S_{wr} = 31$; $S_{gr} = 5$ %
Oil PVT Data	Correlations ^{46,47}
Water PVT Data	$R_{sw} = 0$; $B_w = 1$; $\mu_w = 1.4$ cp
Gas PVT Data	Correlations ⁴⁸
Phase Densities at Surface Condition	$\rho_{os} = 850$; $\rho_{ws} = 1100$; $\rho_{gs} = 1.9$ mg/ml
Rock Compressibility	5×10^{-6} psia ⁻¹
Molecular Diffusion Coefficients	0.044 cm ² /hr
Tortuosity	1.4
Longitudinal Dispersivity	0.06 cm
Cell Yield from Glucose	0.8202 mg/mg
Carbon Dioxide Yield from Glucose	0.0707 mg/mg
Acid Yield from Glucose	0.6575 mg/mg
Alcohol Yield from Glucose	0.1862 mg/mg
Parameters for Bimodal Distribution	$e_1 = 1$; $e_2 = 4$; $m_1 = 2$; $m_2 = 5$; $w=0.8$
Min. and Max. Pore-Throat, and Cell Sizes	$x_{min} = 1$; $x_{max} = 10$; $x_p = 1$ μm
Injected Biomass Concentration	1×10^8 cell/ml
Injected Glucose Concentration	20 mg/ml
Water Injection Rate	50 scc/hr

Table 7.17 Petrophysical Properties for Core #4

Properties	Values
Core Length	29.85 cm
Core Diameter	5.08 cm
Pore Volume	85 ml
Porosity	14 %
Absolute Permeability	106 md
Permeability to Oil	74 md
Permeability to Water	22 md
Connate Water (saturation)	30 ml (35 %)
Residual Oil (saturation)	26 ml (31 %)

Table 7.18 Experimental Results for Core #4

Treatment Number	Oil Recovery (ml)	Gas Recovery (ml)	Surfactant Produced		PRF (%)
			(unit)	(mg) ^a	
1	1	0	132	0.121	105
2	2	0	116	0.106	118
3	2	0	79	0.072	109
4	0.5	0	57	0.052	96
5	<0.5	0	46	0.042	91

a: Conversion factor = 1092 unit/mg.

8. CONCLUSIONS AND RECOMMENDATIONS

8.1 Conclusions

1. A three-dimensional, three-phase, multiple-component numerical simulator was developed to investigate transport and growth of microorganisms in porous media and impacts of microbial activities on enhanced oil recovery processes.
2. The simulator was verified by comparison of the numerical solutions from this simulator with the results from analytical equations, a commercial simulator, and laboratory experiments.
3. The model verification indicated that the simulator was capable of quantifying microbial transport and metabolism in porous media and predicting additional oil recovery as results of microbial processes.
4. Case studies conducted using this simulator showed that the major mechanisms for oil recovery by MEOR processes include: (1) improvement of sweep efficiency due to microbial plugging and mobility control, and (2) an increase in capillary number due to reduction of interfacial tension between oil and water phases.
5. Simulation results suggested that gases generated during microbial growth and metabolism could not be expected to contribute much to additional oil recovery by MEOR processes.

8.2 Recommendations

1. Effects of produced acids and alcohols, and pH on the MEOR processes should be investigated.
2. Change in wettability of rock during the MEOR processes and its impact on oil recovery should be examined.

9. NOMENCLATURE

- a_k = Langmuir adsorption constants for component k
- b_k = Langmuir adsorption constants for component k
- B_ℓ = Formation volume factor for phase ℓ (rcc/scc)
- C_i = Concentration for inhibitor i (mg/scc)
- C_k = Concentration for flowing component k (mg/scc)
- C_{ks} = Concentration for sorbed component k (mg/scc)
- C_s = Concentration for substrate s (mg/scc)
- $C_{6,\min}$ = Minimum concentration for biosurfactant
- $C_{6,\max}$ = Maximum concentration for biosurfactant
- C_g = Compressibility for gas phase (psia⁻¹)
- C_o = Compressibility for oil phase (psia⁻¹)
- C_r = Compressibility for rock (psia⁻¹)
- C_t = Total compressibility (psia⁻¹)
- C_w = Compressibility for water phase (psia⁻¹)
- ΔC_{\max} = Maximum relative change in component concentration (fr)
- ΔC_{\lim} = Up limit for relative change in component concentration (fr)
- \bar{D}_{wk} = Dispersion tensor for component k in water phase (cm²/hr)
- D_k = Molecular diffusion coefficient for component k (cm²/hr)
- $D_{kw,mm'}$ = Element of dispersion tensor for component k (cm²/hr), m, m' = X, Y, Z
- e_1, e_2 = Exponent parameters for bimodal distribution
- e_s = Exponent parameters for IFT
- f = Flow efficiency factor

- $K_{b/s}$ = Saturation constant for biomass growth from substrate (mg/scc)
 $K_{p/s}$ = Saturation constant for formation of product from substrate (mg/scc)
 K_i = Inhibition coefficient for inhibitor i (mg/scc)
 K_c = Chemotactic coefficient (cm²/hr)
 K_r = Coefficient for bacterial retention (cm⁻¹)
 K_d = Coefficient for bacterial detachment (cm/psia/hr)
 K_{pol} = Coefficient for computing viscosity for biopolymer solution (cp.scc/mg)
 $\bar{\bar{K}}$ = Diagonal permeability tensor (md)
 K_m = Permeability in m -direction (md), $m = X, Y, Z$
 $K_{r\ell}$ = Relative permeability for phase ℓ (md/md)
 $K_{r\ell}^h$ = Relative permeability for phase ℓ at high capillary number (md/md)
 $K_{r\ell}^w$ = Relative permeability for phase ℓ at low capillary number (md/md)
 m_1, m_2 = Exponent parameters for bimodal distribution function
 m_s = Coefficient of maintenance energy provided by consuming substrate s (hr⁻¹)
 \tilde{m}_ℓ = Mass injection/production rate per unit rock bulk volume for phase ℓ (mg/ml/hr)
 $N_{c\ell}$ = Capillary number for phase ℓ
 $N_{c\ell}^h$ = High capillary number for phase ℓ
 $N_{c\ell}^w$ = Low capillary number for phase ℓ
 p_{cow} = Oil-water capillary pressure (psia)
 p_{cgo} = Gas-oil capillary pressure (psia)
 p_{cow}^w = Oil-water capillary pressure at low capillary number (psia)
 p_ℓ = Pressure for phase ℓ (psia)
 $p_{wf,z}$ = Bottom hole pressure at layer z (psia)
 Δp_{max} = Maximum relative change in block pressure (fr)
 Δp_{lim} = Up limit for relative change in block pressure (fr)

- δp = Perturbation in pressure (psia)
 Q_ℓ = Mass injection/production rate per unit bulk volume for phase ℓ (mg/scc/hr)
 q_ℓ = Volumetric injection/production rate for phase ℓ (scc/hr)
 $q_{\ell,z}$ = Volumetric injection/production rate for phase ℓ at layer z (scc/hr)
 q_{g2} = Volumetric production rate for N_2 generated from MEOR process (scc/hr)
 q_{g3} = Volumetric production rate for CO_2 generated from MEOR process (scc/hr)
 R_k = Growth, production, or consumption rate for component k (mg/scc/hr)
 R_{bf} = Growth rate for flowing bacteria (mg/scc/hr)
 R_{bs} = Growth rate for sorbed bacteria (mg/scc/hr)
 R_r = Bacterial retention rate (mg/scc/hr)
 R_d = Bacterial detachment rate (mg/scc/hr)
 S_ℓ = Saturation for phase ℓ (rcc/rcc)
 $S_{\ell r}$ = Residual saturation for phase ℓ (rcc/rcc)
 $S_{\ell r}^h$ = Residual saturation for phase ℓ at high capillary number (rcc/rcc)
 $S_{\ell r}^w$ = Residual saturation for phase ℓ at low capillary number (rcc/rcc)
 ΔS_{\max} = Maximum relative change in saturation (fr)
 ΔS_{\lim} = Up limit for relative change in saturation (fr)
 R_{so} = Solution gas-oil ratio (scc/scc)
 R_{sw} = Solution gas-water ratio (scc/scc)
 \bar{u}_ℓ = Darcy velocity vector for phase ℓ (cm/hr)
 $u_{\ell m}$ = Element of Darcy velocity for phase ℓ in m -direction (cm/hr), $m = X, Y, Z$
 \bar{u}_c = Chemotactic velocity vector for bacteria (cm/hr)
 V_b = Bulk volume of grid block (scc)
 w = Weighting factor (fr)
 x_{ct} = Critical pore throat size for plugging (μm)

- x_{\min} = Minimum pore throat size (μm)
 x_{\max} = Maximum pore throat size (μm)
 x_{cb} = Cell body size (μm)
 $x_{c\ell}$ = Mass fraction of component c in phase ℓ (mg/mg)
 ΔX = Grid block size in the X-direction (cm)
 ΔY = Grid block size in the Y-direction (cm)
 ΔZ = Grid block size in the Z-direction (cm)
 $Y_{\text{b/s}}$ = factor of yield of bacteria from substrate (mg/mg)
 $Y_{\text{p/s}}$ = factor of yield of product from substrate (mg/mg)

Greek Symbols

- α_e = Empirical parameters for computing critical pore-throat size
 β_e = Empirical parameters for computing critical pore-throat size
 γ_e = Empirical parameters for computing critical pore-throat size
 α_{lw} = Longitudinal dispersivity for water phase (cm)
 α_{tw} = Longitudinal dispersivity for water phase (cm)
 ϕ = Rock porosity (rcc/rcc)
 Φ_ℓ = Potential for phase ℓ (psi/cm)
 μ_ℓ = Viscosity for phase ℓ (cp)
 μ_{bm} = Maximum specific growth rate for bacteria (hr^{-1})
 μ_{pm} = Maximum specific production rate for product p (hr^{-1})
 μ_{pol} = Viscosity for biopolymer solution (cp)
 σ = Pore volume fraction occupied by sessile bacteria (rcc/rcc)
 σ_{\min} = Minimum interfacial tension between oil and water (mN/m)
 σ_{\max} = Maximum interfacial tension between oil and water (mN/m)

- σ_{ow} = Interfacial tension between oil and water (mN/m)
 ρ_{bsc} = Density for bacteria at surface condition (mg/scc)
 ρ_{ksc} = Density for component k at surface condition (mg/scc)
 ρ_{osc} = Density for oil at surface condition (mg/scc)
 ρ_{wsc} = Density for water at surface condition (mg/scc)
 ρ_{gsc} = Density for gas at surface condition (mg/scc)
 λ_{ℓ} = Mobility for phase ℓ (md/md/cp)
 $\bar{\gamma}_z$ = Average specific weight for fluids at producer at layer z (mg/scc)
 $\gamma_{inj,z}$ = Specific weight for injected fluid at injector at layer z (mg/scc)

Subscript

- b** = Bacteria
k = 1, 2, 3, , 10, representing components such as bacteria, nitrogen, carbon dioxide, acid, alcohol, surfactant, polymer, carbon-nutrient, nitrogen-nutrient #1, nitrogen-nutrient #2, respectively
ks = Sorbed component k
 ℓ = Phase such as oil, water, or gas
p = Product such as nitrogen, carbon dioxide, acid, alcohol, surfactant, or polymer
s = Substrate such as carbon-nutrient, nitrogen-nutrient #1, and nitrogen-nutrient #2
o, w, g = Oil, water, and gas phases
X, Y, Z = Orthogonal geometrical directions
x,y,z = Coordinates in X-, Y-, and Z-directions
